## ABSTRACT

The Transiting Exoplanet Survey Satellite (TESS) is providing precise time-series photometry for most star clusters in the solar neighborhood. Using the TESS images, we have begun a Cluster Difference Imaging Photometric Survey (CDIPS), in which we are focusing both on stars that are candidate cluster members, and on stars that show indications of youth. Our aims are to discover giant transiting planets with known ages, and to provide light curves suitable for studies in stellar astrophysics. For this work, we made 159,343 light curves of candidate young stars, across 596 distinct clusters. Each light curve represents between 20 and 25 days of observations of a star brighter than  $G_{Rp} = 16$ , with 30-minute sampling. We describe the image subtraction and time-series analysis techniques we used to create the light curves, which have noise properties that agree with theoretical expectations. We also comment on the possible utility of the light curve sample for studies of stellar rotation evolution, and binary eccentricity damping. The light curves, which cover about one sixth of the galactic plane, are available at [archive.stsci.edu/prepds/cdips](http://archive.stsci.edu/prepds/cdips).

## 1. INTRODUCTION

Each of the several thousand star clusters of the Milky Way is a gift to astrophysics, providing a sample of stars that vary widely in mass but all have approximately the same age and composition. Time-series photometry of clusters has many applications. By measuring rotation periods over a range of ages, we can study the angular momentum evolution of stars and improve our ability to determine stellar ages through gyrochronology (*e.g.*, Skumanich 1972; Barnes et al. 2015; Meibom et al. 2015; Curtis et al. 2019). By measuring the eccentricity distribution of binary stars as a function of age, we can study the tidal circularization process (Meibom & Mathieu 2005; Milliman et al. 2014; Price-Whelan & Goodman 2018). The detection of eclipsing binaries (EBs) can also lead to the precise determination of the absolute dimensions of the stars and stringent tests of stellar-evolutionary models (Luhman 2012; Stassun et al. 2014; Kraus et al. 2015). Finally, transiting exoplanets discovered in clusters can shed light on the timescales for processes in planet formation, evolution, and migration (Fortney et al. 2007; Mann et al. 2016;

David et al. 2016), as well as on the effects of metallicity (Fischer & Valenti 2005; Petigura et al. 2018).

The Transiting Exoplanet Survey Satellite (TESS, Ricker et al. 2015) holds the promise to deliver the most homogeneous and comprehensive cluster photometric survey in history. Based on the cluster membership data of Kharchenko et al. (2013), approximately  $2 \times 10^5$  open cluster members brighter than  $T = 16$  will be observed in the full-frame images (FFIs) over the first two years of TESS. This count includes the Kharchenko et al. “most probable” members, which are stars with kinematic, photometric, and spatial membership probabilities each independently exceeding 61% (Kharchenko et al. 2012). The actual number of stars in clusters is likely larger, as the membership catalogs are not yet complete, even within the nearest kiloparsec (*e.g.*, Röser et al. 2016; Cantat-Gaudin et al. 2018, 2019b; Kounkel & Covey 2019; Sim et al. 2019).

A major barrier to deriving precise photometry from the TESS images is the relatively poor angular resolution (21'' per pixel). The problems with crowding and complex backgrounds are so severe that the TESS Candidate Target List deprioritizes 2-minute targets within 15° of the galactic

Corresponding author: L. G. Bouma  
[luke@astro.princeton.edu](mailto:luke@astro.princeton.edu)

plane<sup>1</sup> (Stassun et al. 2018, 2019). This decision was made because the large pixel size and the high stellar surface density make aperture photometry unreliable. By consequence, most stars in clusters, which are usually near the galactic plane, will go unprocessed by the official *TESS* data reduction pipeline.

One way to quantify the blending problem is to determine what fraction of the total flux in a photometric aperture is contributed by a particular target star. Aperture photometry is reliable when this fraction is close to unity. Difference imaging (Alard & Lupton 1998; Miller et al. 2008), in our group’s experience, can be viable down to crowding fractions of 10%. Based on the Kharchenko et al. (2013) cluster membership data and the density of background stars, we calculated that the median dilution fraction is 0.13, for cluster stars with  $T < 16$  and an aperture radius of 2 pixels. Thus, for at least  $\sim 10^5$  cluster stars, difference imaging may be advantageous.

Difference imaging avoids the primary effects of blending through forced-aperture photometry. In this method, the pixel coordinates of stars are calculated from an astrometric solution, and the reference fluxes are determined from a calibrated catalog magnitude-to-flux relation (see § 3.5.3). The deviation from the reference flux is measured on the difference image. Assuming that only a single source is variable, blended neighbor stars only act to increase Poisson noise, down to the angular resolution of the source catalog used to determine the reference flux. This is a major benefit of performing image subtraction in crowded fields.

We have therefore begun to apply difference imaging to the *TESS* FFIs, with a focus on any star that could be a cluster member. We are also including some stars that we suspect are young due to combined photometric and astrometric indicators. A major motivation for this effort is to discover giant transiting planets with known ages. The focus of the present study however is to describe our methods, and to produce a general-purpose dataset applicable for studies both in exoplanetary and also stellar astrophysics.

For the remainder of this work, we adopt the term “star cluster”, or simply cluster, to refer to a coeval group of stars. This includes open clusters, as well as the moving groups and stellar associations that have been discovered since the late 1990s (Zuckerman & Song 2004).

The plan of action is as follows. In § 2, we describe how target stars were selected. We then present the photometric and image processing methods we used to produce light curves for these stars (§ 3). In *TESS* Sectors 6 and 7, these methods yielded 159,343 light curves, and in § 4.1 we summarize their statistical properties. We then give an example of how to use the data to identify pulsating stars, eclipsing binaries, and transiting planets (§ 4.2). We close in § 5 with

<sup>1</sup> During the first year of *TESS* observations, objects within  $15^\circ$  of the galactic plane were deprioritized. Starting in the second year of observations, the cutoff changed to objects within  $10^\circ$  of the galactic plane (Stassun et al. 2019).

a summary of our findings, and discuss them with an eye towards the studies we hope this and further data processing will enable.

## 2. METHOD: STAR SELECTION

The main aim of the CDIPS project is to increase the number of cluster stars for which photometric time-series are available, and thereby facilitate studies of exoplanetary and stellar processes across different times and stellar environments. A key step is therefore to define a sample of stars that are thought to be young, or members of clusters, or both.

A homogeneous membership calculation for every known cluster is a large undertaking, and currently falls outside our scope. So too is a homogeneous search for young stars across the galaxy. Instead, we have opted to collect and concatenate catalogs from the literature. We then use the resulting meta-catalog to identify target stars within the *TESS* images.

The criteria for inclusion in our target star list are necessarily heterogeneous across different catalogs. We aim for completeness, not accuracy. If there has been a claim in the literature that a star should be considered a cluster member, or a young star, we would like to err on the side of reporting a light curve for the star. For stars that are photometrically interesting, we can then perform post-hoc quality checks using Gaia-DR2 astrometry and photometry to assess cluster membership and youth.

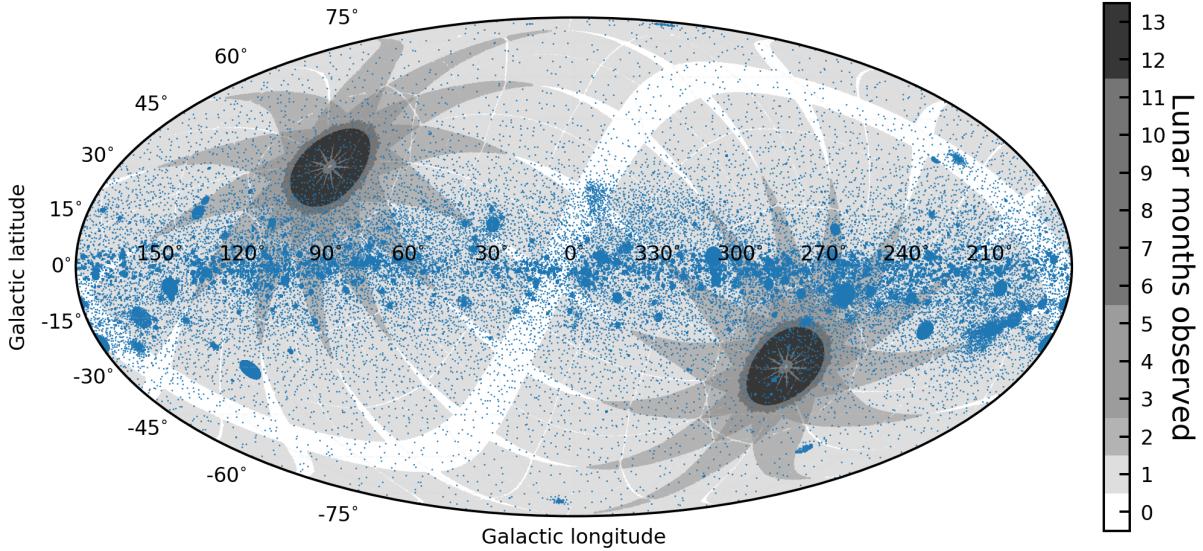

First, we describe the catalogs we used to identify members of open clusters (§ 2.1). Then, we discuss the catalogs we used to identify members of moving groups, stellar associations, and more generally young stellar populations (§ 2.2). In § 2.3 we give summary statistics for the entire sample of about one million target stars, and we list the targets in Table 1.

### 2.1. Big catalogs: open clusters

At the time of our analysis, two relatively large, homogeneous cluster memberships studies had been performed using Gaia-DR2: those by Cantat-Gaudin et al. (2018) and Gaia Collaboration et al. (2018a). There were also two large membership studies pre-dating Gaia-DR2 based on proper motion and photometric catalogs: the studies of Kharchenko et al. (2013) and Dias et al. (2014).

*Gaia-derived OC memberships*—Cantat-Gaudin et al. (2018) used an unsupervised membership assignment algorithm (Krone-Martins & Moitinho 2014) to identify cluster members using Gaia-DR2 positions, proper motions, and parallaxes. They used Gaia photometry and radial velocities to verify the membership claims. From their Table 2, we collected 401,448 cluster members, in 1229 clusters, down to their limiting magnitude of  $G = 18$ .

Gaia Collaboration et al. (2018a) reported members of a smaller, more select group of well-studied open clusters. From their Table A1, we collected 40,903 cluster members, in 41 open clusters, mostly within 500pc. While this work also included memberships for globular clusters, we omitted them from consideration.

**Figure 1.** Target star positions (blue) and nominal TESS observing footprint (gray). Target stars are either candidate members of clusters, or else have other youth indicators (see § 2). Most will be observed for one or two lunar months during the TESS Prime Mission. Camera 1 is centered at  $(l, b) = (203^\circ, -6^\circ)$  and  $(218^\circ, 15^\circ)$  in Sectors 6 and 7, respectively.

Given the high quality of Gaia-DR2 astrometry, these two membership sources are our most reliable sources of membership information. In our photometric reduction, our default identifier for all sources is correspondingly the Gaia-DR2 `source_id`. The TESS Input Catalog (TIC) data for each target star are then collected using the Gaia-DR2 source identifier (Stassun et al. 2018, 2019).

*Pre-Gaia OC memberships*—Kharchenko et al. (2013) used proper motions calculated in PPMXL (Röser et al. 2010, a combination of USNO-B1.0 and 2MASS astrometry) and near-infrared photometry from 2MASS (Skrutskie et al. 2006) to report the existence of 2859 open clusters and stellar associations. We omitted globular clusters by excluding any entry of type ‘g’. We selected the most probable cluster members (“ $1\sigma$  members”) using the combined photometric, kinematic, and spatial criteria described by Kharchenko et al. (2012). Then, to obtain *Gaia*-DR2 source identifiers for the members, we performed a crossmatch for Gaia-DR2 sources within 5 arcseconds of the listed positions. To improve the quality of the cross-match, we used the 2MASS photometry to predict the  $G$ -band magnitudes<sup>2</sup>, and required that the measured  $G$ -magnitude fall within 2 magnitudes of the predicted  $G$ -magnitude. If multiple neighbors matched the position and magnitude constraints, we took the nearest spatial neighbor as the match. From 373,226 stars, this yielded a unique best neighbor for 352,332 stars (94.4% of the sample), and a choice between two neighbors for 17,774 stars.

<sup>2</sup> See [https://gea.esac.esa.int/archive/documentation/GDR2/Data\\_processing/chap\\_cu5pho/sec\\_cu5pho\\_calibr/ssec\\_cu5pho\\_PhotTransf.html](https://gea.esac.esa.int/archive/documentation/GDR2/Data_processing/chap_cu5pho/sec_cu5pho_calibr/ssec_cu5pho_PhotTransf.html), (accessed 2019-03-29), or Carrasco et al. (2016)

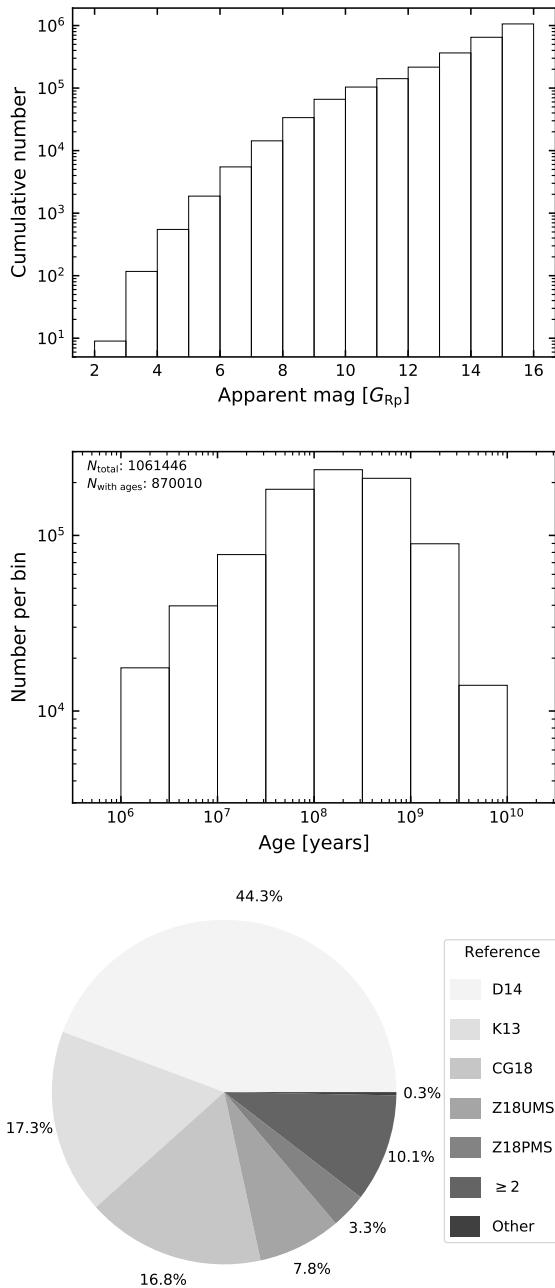

The second (non-*Gaia* derived) open cluster membership catalog we used was the Dias et al. (2014) catalog, which was based on UCAC4 proper motions acquired by the US Naval Observatory (Zacharias et al. 2013). From their 1805 reported open clusters, we selected sources with quoted membership probability above 50%. To obtain Gaia-DR2 source identifiers for the members, we performed a similar cross-match, looking for sources within 5 arcseconds of the listed positions, and within  $\pm 2$   $G$ -band magnitudes of the prediction. From 2,034,269 stars, this yielded a unique best neighbor for 1,828,630 stars (89.9% of the sample), and a choice between two neighbors for 8.7% of the remaining sample.

The distributions of various cross-matching statistics are shown in Figure 3. The distances between matches is typically below 1 arcsecond. The Dias et al. catalog shows stronger crowding effects at the faint end than the Kharchenko et al. catalog, and likely has a larger number of false matches. At their faint ends, both catalogs show a tendency for true  $G$ -band magnitudes to be larger than predicted  $G$ -band magnitudes, presumably due to dust reddening.

## 2.2. Smaller catalogs: moving groups and stellar associations

Stars in moving groups and stellar associations are interesting for similar reasons as stars in open clusters. Relative to open cluster members though, stars in moving groups are usually closer, brighter, and exist in less crowded environments.

To identify stars in these types of groups, we matched the following studies against Gaia-DR2: Gagné et al. (2018a), Gagné et al. (2018b), Gagné & Faherty (2018), Kraus et al. (2014), Röser et al. (2011), Bell et al. (2017), Rizzuto et al. (2011), Oh et al. (2017), and Zari et al. (2018). The methods applied in these studies vary from kinematic analyses, to as-

**Figure 2.** Target star statistics. *Top*. Cumulative counts as a function of apparent Gaia  $Rp$ -band magnitude. *Middle*. Histogram of target star ages, for the subset of stars with ages matched against Kharchenko et al. (2013). *Bottom*. Provenance of cluster membership. Percentages are relative to the  $N_{\text{total}} = 1,061,446$  target stars, which are listed in Table 1. Symbols are as follows. D14 is Dias et al. (2014). K13 is Kharchenko et al. (2013). CG18 is Cantat-Gaudin et al. (2018). Z18 is Zari et al. (2018), with upper main sequence and pre-main-sequence samples sub-divided. “ $\geq 2$ ” indicates at least two authors reported a star as a candidate cluster member.

photometric analyses included Gaia-DR1 parallaxes, to photometric searches for infrared excesses, to spectroscopic studies including RVs, H $\alpha$  emission, and Li absorption.

For the Gagné et al. catalogs, a large number of the stars have high proper motions. However, some of the stars do not have reported proper motions. To perform the cross-match, we searched the Gaia-DR2 archive for sources within 10 arc-seconds of the listed positions (propagated to the Gaia-DR2 J2015.5 epoch, if the proper motions were available, otherwise simply using the listed J2000 positions). We also imposed a  $G < 18$  cut on any putative matches. We then chose the nearest neighbor by spatial separation. Of 3012 moving group members collected from the three combined Gagné et al. catalogs, this procedure yielded 2702 matches.

The Kraus et al. (2014), Röser et al. (2011), and Bell et al. (2017) studies reported members in Tucana-Horologium, the Hyades, and 32 Ori respectively. Applying the same procedure as for the Gagné catalogs gave 187, 684, and 119 matches respectively, compared to 205, 724, and 141 initially reported members. Note that Kraus et al. (2014) found that only  $\sim 70\%$  of their listed members have spectroscopic indicators consistent with membership in Tucana-Horologium.

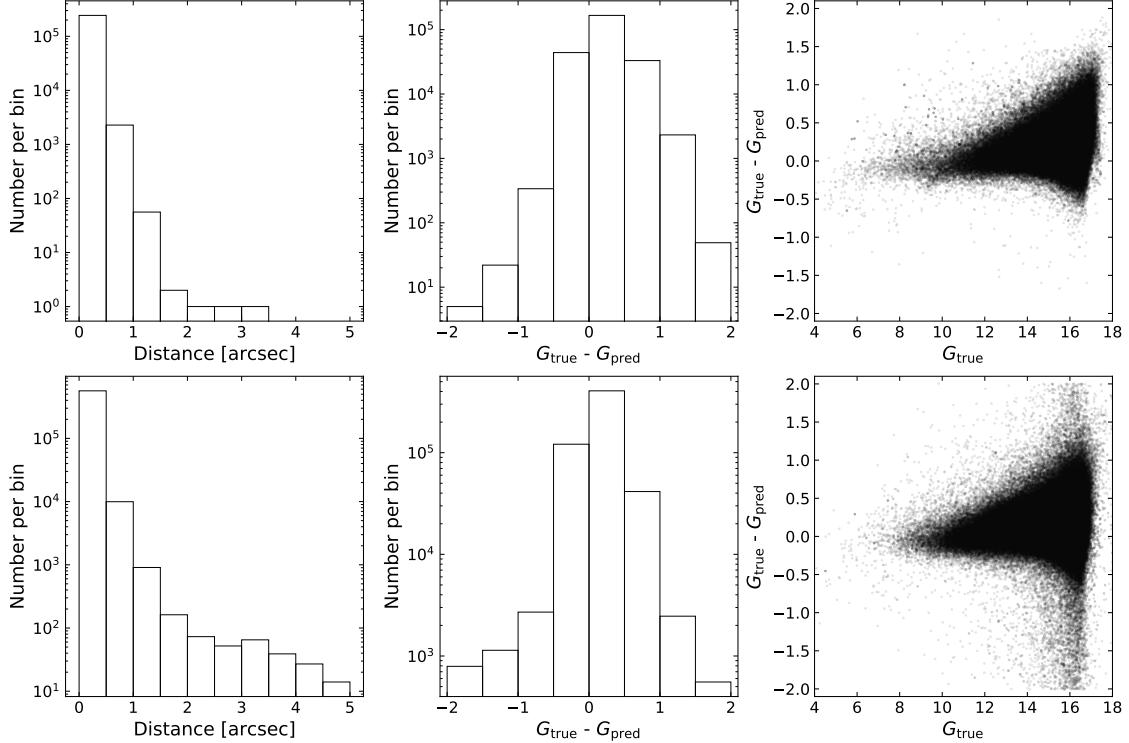

Rizzuto et al. (2011) focused on a single group: the Sco OB2 association. We used their reported Hipparcos identifiers, and matched against the *Gaia* archive’s `hipparcos2_best_neighbour` table, which gave 319 nearest-neighbor stars from 436 candidate members.

Oh et al. (2017) searched for comoving stars in the  $\approx 2$  million stars that appear in both the Tycho-2 and Gaia-DR1 catalogs. They found many wide binaries, and also identified a large number of comoving groups. We chose the 2,134 stars that they reported were in groups with sizes of at least 3 stars. Using their Gaia-DR1 source identifiers, we matched against the *Gaia* archive’s `drl_neighbourhood` table, which gave 1,881 nearest-neigbor stars in groups of at least three stars (Marrese et al. 2019).

Finally, Zari et al. (2018) constructed a sample of young stars within 500 pc using data from Gaia-DR2. Two subsamples were made: an upper main sequence (MS) sample, with 86,102 stars, and a pre-MS sample, with 43,719 stars. Each was created from a careful combination of distinct astrometric and photometric cuts. These stars are the youngest, closest stars, spread across star-forming complexes in Sco-Cen, Orion, Vela, Taurus, and other regions of the sky. Though most of these stars are not directly identified with moving groups or open clusters, their reported youth and proximity to star forming regions justifies their inclusion in our search sample.

### 2.3. Summary of target stars

After collecting the aforementioned lists, we merged them into a single table. We queried Gaia-DR2’s `gaia_source` table to retrieve each star’s apparent  $G$ ,  $G_{Rp}$ , and  $G_{Bp}$  magnitudes, as well as their astrometric measurements  $(\alpha, \delta, \mu_\alpha, \mu_\delta, \pi)$ . Finally, we required that  $G_{Rp} < 16$ , which is roughly the level for which the 1-hour photometric precision of TESS is predicted to be 1% (Ricker et al. 2015).

**Figure 3.** *Top.* Quality diagnostics from cross-matching [Kharchenko et al. \(2013\)](#) cluster members against Gaia-DR2. A histogram of the distances between matched stars is on the left; a histogram of the difference between the true  $G$ -band magnitude and that predicted from 2MASS photometry is in the middle; a scatter plot of the same magnitude difference as a function of  $G$ -band magnitude is on the right. *Bottom.* Same, but cross-matching [Dias et al. \(2014\)](#) cluster members to Gaia-DR2.

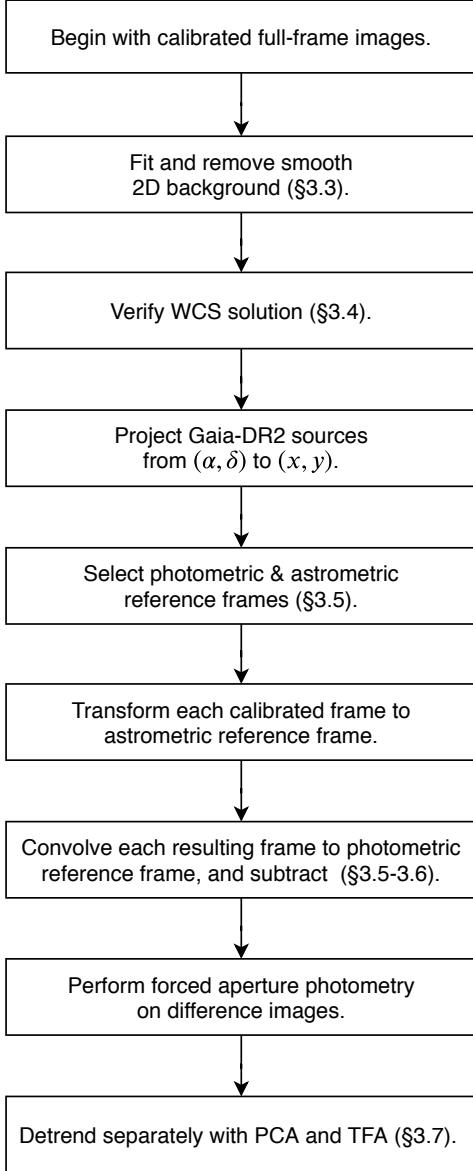

The resulting CDIPS target star list, consisting of 1,061,447 unique stars from 13 distinct catalogs, is given in Table 1. The cumulative distribution of target star brightnesses, as well as a histogram of the ages, is shown in Figure 2. Relative to field stars, our target star sample is young, with a most probable age of 100 Myr.

Figure 2 also shows the relative fraction of stars from each catalog. The largest number of stars come from [Dias et al. 2014](#) (44.3%), [Kharchenko et al. 2013](#) (17.3%), [Cantat-Gaudin et al. 2018](#) (16.7%), and [Zari et al. 2018](#) (11.1%, of which 7.8% are OBA stars, and 3.3% are pre-MS stars). 107,647 of the stars, or about 10% of the collection, have cluster memberships reported by multiple authors. Since the membership probability calculations often use independent data and methods, agreement between multiple investigators on a given star's cluster membership is a helpful indication of it being a member.

Different catalogs have different standards for deciding which stars are members. For the [Dias et al. \(2014\)](#) catalog, their membership calculation included only spatial and kinematic information, and we used a relatively low probability threshold when including their stars (based on the criteria [Dias et al. 2014](#) used for their star counts). The [Kharchenko et al. \(2013\)](#) catalog combined spatial, kinematic, and photometric information to derive their membership probabilities. We also used a more restrictive membership probabil-

ity cut (again, following the criteria they used for their star counts), so this sub-sample is likely less contaminated with field interlopers. [Cantat-Gaudin et al. \(2018\)](#) used spatial, kinematic, and astrometric information from Gaia-DR2. Despite the lack of photometric information, the quality of the Gaia data suggest that the field contamination rate will be lowest for the [Cantat-Gaudin et al. \(2018\)](#) sample.

To assign unique cluster names, we adopted the name given by [Kharchenko et al. \(2013\)](#) whenever possible. Appendix B describes how this was done in detail. For moving groups not identified by [Kharchenko et al. \(2013\)](#), we used the constellation-based naming convention from [Gagné et al. \(2018b\)](#). Otherwise, we used the name reported by the original catalog claiming membership. This process reduced 16,425 name variants down to 3,216 unique cluster names. Though we have made every effort to avoid duplicates, a small number may remain, so we advise inspection of the `cluster` column as well as the references given in the `reference` column rather than using the `unique_cluster_name` column to analyze individual objects of interest. Nonetheless, 87.7% of the ~million unique target stars are matched to clusters named by [Kharchenko et al. \(2013\)](#), and 88.8% are assigned a cluster name. The remainder are mostly young stars from [Zari et al. \(2018\)](#). Ages and their uncertainties were then assigned using the parameters reported by [Kharchenko et al. \(2013\)](#).

**Figure 4.** Conceptual overview of photometric reduction pipeline. Details are given in § 3.

### 3. METHOD: PHOTOMETRY

#### 3.1. Overview

To reduce the TESS images to light curves, we adopted a difference imaging approach. The overall method is in the spirit of the pipelines developed by Pál (2009), Huang et al. (2015), Soares-Furtado et al. (2017), Oelkers & Stassun (2018) and Wallace et al. (2019). Figure 4 shows a conceptual overview of our pipeline. Most modules have been developed over the past decade to reduce images taken by the Hungarian Automated Telescope (HAT) network (Bakos 2018). The work of Pál (2009), embodied in the `fitsfh` software package, was an especially crucial component. The specific high-level framework we used for this reduction was

adapted from a pipeline under development for the HATPI project ([hatpi.org](http://hatpi.org)). The code is available online<sup>3</sup>, and the pipeline reference is Bhatti et al. (2019).

We begin our processing with the calibrated full frame images produced by the Science Processing Operations Center at NASA Ames (§ 3.2). We then perform a collection of preparatory steps, including source extraction of bright stars, astrometric verification, and coarse simple aperture photometry of bright stars (§ 3.3). Using the information collected from these initial steps, we select an astrometric reference frame to which we transform all of the calibrated images. To construct a photometric reference frame, we first convolve a subset of the frames to have identical stellar profiles, and then stack them. Finally, we subtract each target frame from the photometric reference frame (§ 3.5). We perform aperture photometry on the subtracted images using positions projected onto the frame from the Gaia-DR2 source catalog. The resulting differential flux measurements are converted to total flux measurements using photometric information from Gaia-DR2 to determine the total flux of each source on the reference image. We detrend the resulting light curves (§ 3.7). The resulting white noise and red noise properties of the light curves, and a few interesting cases of variability, are explored in § 4.

#### 3.2. Observations

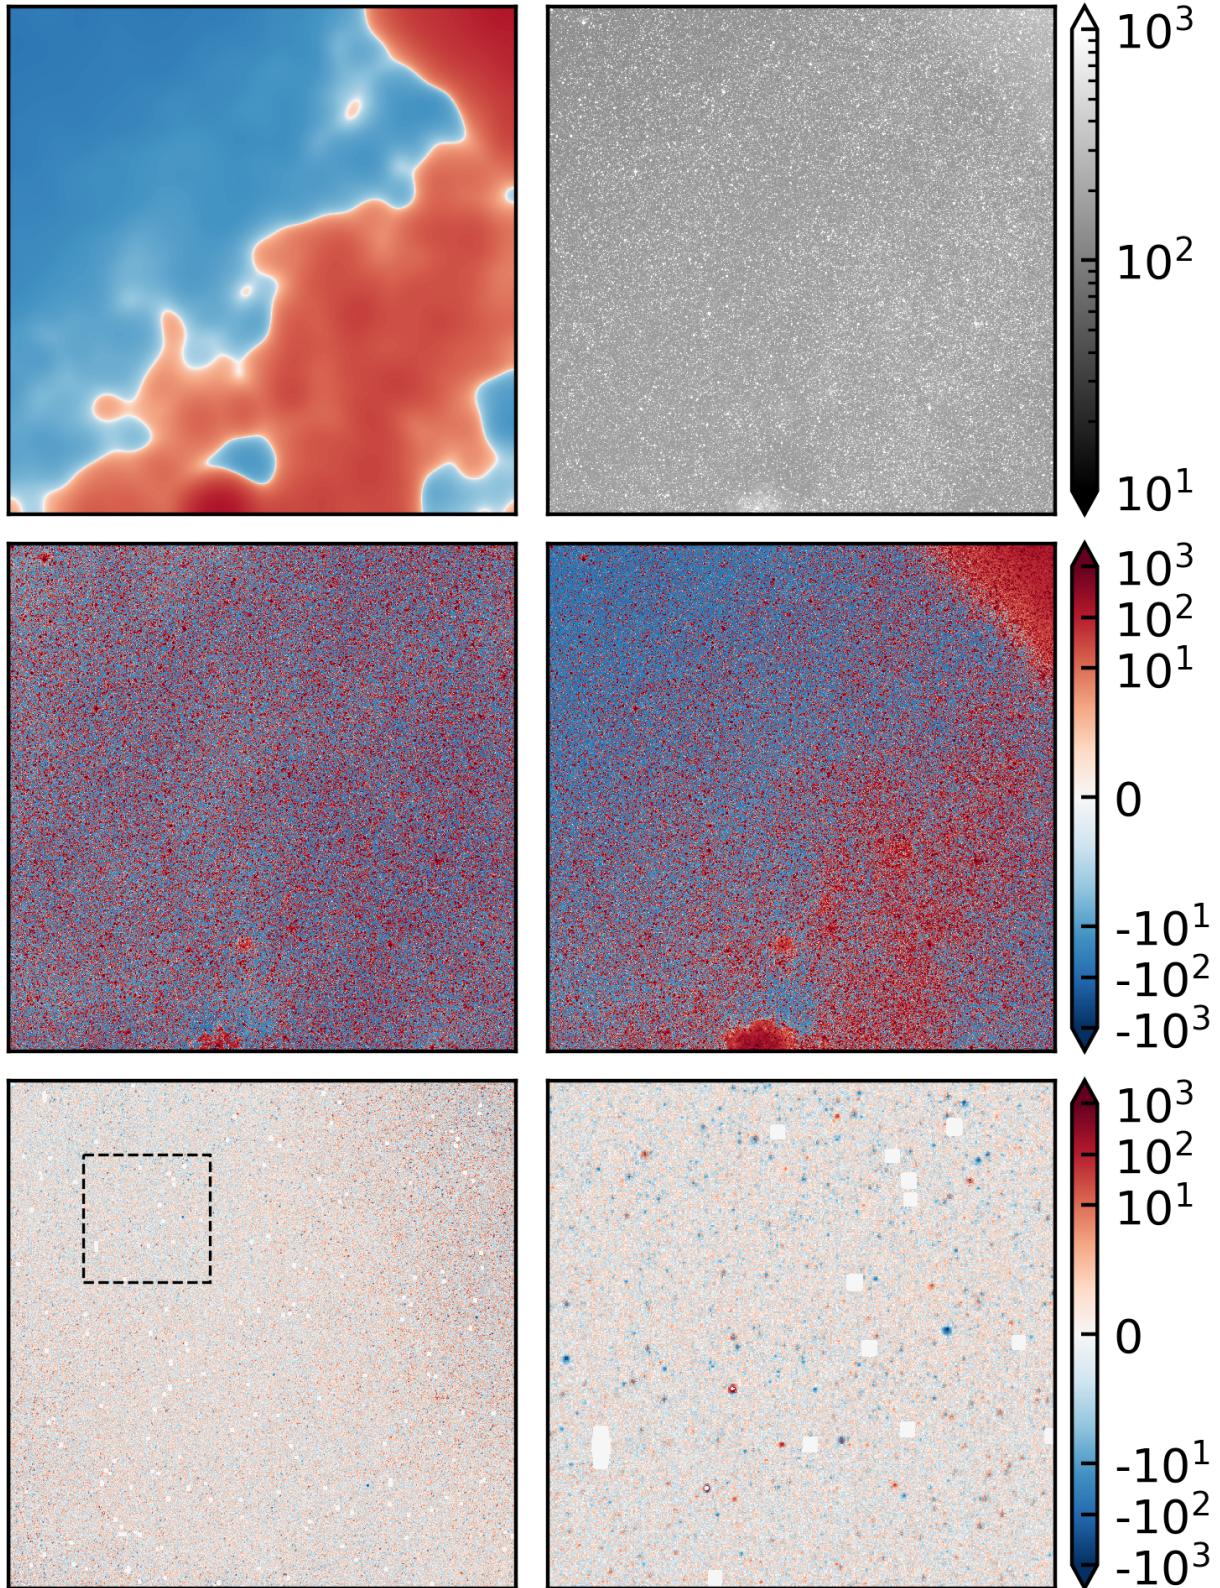

The TESS spacecraft began science operations on July 25, 2018. To keep its cameras pointed opposite the Sun, the spacecraft advances by  $\approx 28$  degrees east in ecliptic longitude every lunar month. Data acquired throughout each one-month “sector” are downlinked at spacecraft perigee through the Deep Space Network. Descriptions of the spacecraft’s design and operations are given by Ricker et al. (2015) and Vanderspek et al. (2018).

For us, the main data product of interest is the calibrated full frame image (FFI). Each TESS camera is read out every 2 seconds. The resulting pixel values are averaged by the onboard computer into 30 minute exposures. An on-board cosmic ray mitigation algorithm is applied (Vanderspek et al. 2018, §5.1). Once transmitted to the ground, the raw images are calibrated by the Science Processing Operations Center (SPOC). The calibration process includes an overscan, bias, and dark current correction, and also divides out a flat field. Details are discussed by Clarke et al. (2017), and the resulting science data products are described by Tenenbaum & Jenkins (2018).

We perform our processing using the calibrated images, the corresponding uncertainty images, and the associated headers. The spacecraft has four cameras, and each camera has four CCDs. In the following analysis, all image-level operations are performed on individual CCD images, so that at any instant of time there are 16 images that require analysis.

Sectors 1–5 mainly covered portions of the sky away from the galactic plane. Consequently, fewer than 2% of the

<sup>3</sup> [github.com/waqasbhatti/cdips-pipeline](https://github.com/waqasbhatti/cdips-pipeline), commit 7175c48.

**Figure 5.** Stages of image processing for an image obtained during the middle of an orbit. Counts are in ADU. *Top right.* Calibrated image. *Top left.* Smooth background estimate. *Middle right.* Calibrated image minus its median pixel value. *Middle left.* Calibrated image minus smooth background. *Bottom left.* Difference image. *Bottom right.* Zoom of difference image, corresponding to the square with dashed lines. Each image is  $(2048 \times 2048)$  pixels, except for the bottom-right image, which is  $(512 \times 512)$ . All images except the top-right have identical color maps. The sector, camera, and CCD are (6, 1, 2).

CDIPS target stars were observed in the first five TESS sectors. Although a few interesting clusters are present in these observations (*e.g.*, Blanco 1, NGC 2516, NGC 1901), for the present work we opted to focus on Sectors 6 and 7, for which there were more stars of interest. Sector 6 began on December 12, 2018 (space orbit #19). Sector 7 concluded on February 1, 2019. Combined, the two sectors cover galactic longitudes from roughly  $200^\circ$  to  $280^\circ$ , with coverage within  $\pm 20^\circ$  of the galactic plane (Figure 1).

### 3.3. Image preparation & background removal

Before we can perform any kind of photometry, a few janitorial tasks are required. First, we convert the multi-extension calibrated FITS image from MAST into a single-extension FITS image, and trim the image to remove virtual rows and columns using the SCIROWS, SCIROWE, SCCSA, and SCCED header values.

In order to account for the background variations present in some frames due to scattered light from the Earth and Moon (see Vanderspek et al. 2018, §7.3.1–7.3.4), we determine and subtract a model of the large-scale background. We do this by temporarily masking out pixels more than  $2\sigma$  from the image median, and then pass a  $48 \times 48$  median box filter over each pixel in the image, with reflective boundary conditions. The resulting background estimate has low-amplitude structure over spatial scales of a few pixels. We then blur the model image with a gaussian kernel of size 48 pixels, which produces a smooth background estimate. These steps also remove low-level vignetting in the corners of many images, which remains even after flat-fielding (see Vanderspek et al. 2018, §7.3.5). The results are shown in the upper four panels of Figures 5 and 6. Features with spatial scales smaller than  $\approx 48$  pixels remain, but large scale patterns of scattered light are removed.

After subtracting the background, we mask out saturated pixels using a fixed saturation level of  $8 \times 10^4$  analog-to-digital units (ADU). This value was chosen based on the onset of bleeding charge trails in the images, and is slightly greater than the saturation level of  $2 \times 10^5$  electrons, or about  $4 \times 10^4$  ADU, reported by Vanderspek et al. (2018). As a consequence, we do not analyze stars brighter than  $T \approx 6.5$ . As described by Pál (2009), the pixel masks are metadata attached to the image file, and are only applied to the pixel values during the specific image processing steps in which they are necessary (*e.g.*, convolution). We also extend the masks beyond purely saturated pixels to “bloomed” pixels horizontally and vertically adjacent to the saturated pixels (see Figure 6 of Pál 2009).

Finally, for frames with the DQUALITY bit-flag corresponding to the “momentum dumps” and “coarse pointing modes” described by Vanderspek et al. (2018), we omit the entire frame. This removes on average a few frames per sector, out of about one thousand. Through visual inspection, we see that the stars on these frames are extremely smeared, and are unlikely to produce useful science data. In addition,

we use the sector-specific data release notes<sup>4</sup> to identify further times with anomalous spacecraft performance, which we omit from consideration. This included three days at the beginning of Sector 6 dedicated to acquiring pixel response function data. There were no additional gaps in Sector 7.

### 3.4. Metadata collection & WCS verification

After preparing the images, we perform some initial analysis steps to produce metadata needed during image subtraction.

First, we perform source extraction on the thousand or so brightest, non-saturated stars in each image. This is done using a `fitsh` module, `fistar`. We derive centroid positions for the stars, and simultaneously fit elliptical gaussians to their profiles, yielding the shape parameters  $(s, d, k)$ , where the flux  $f$  as a function of position  $(x, y)$  in the CCD image plane is assumed to take the form

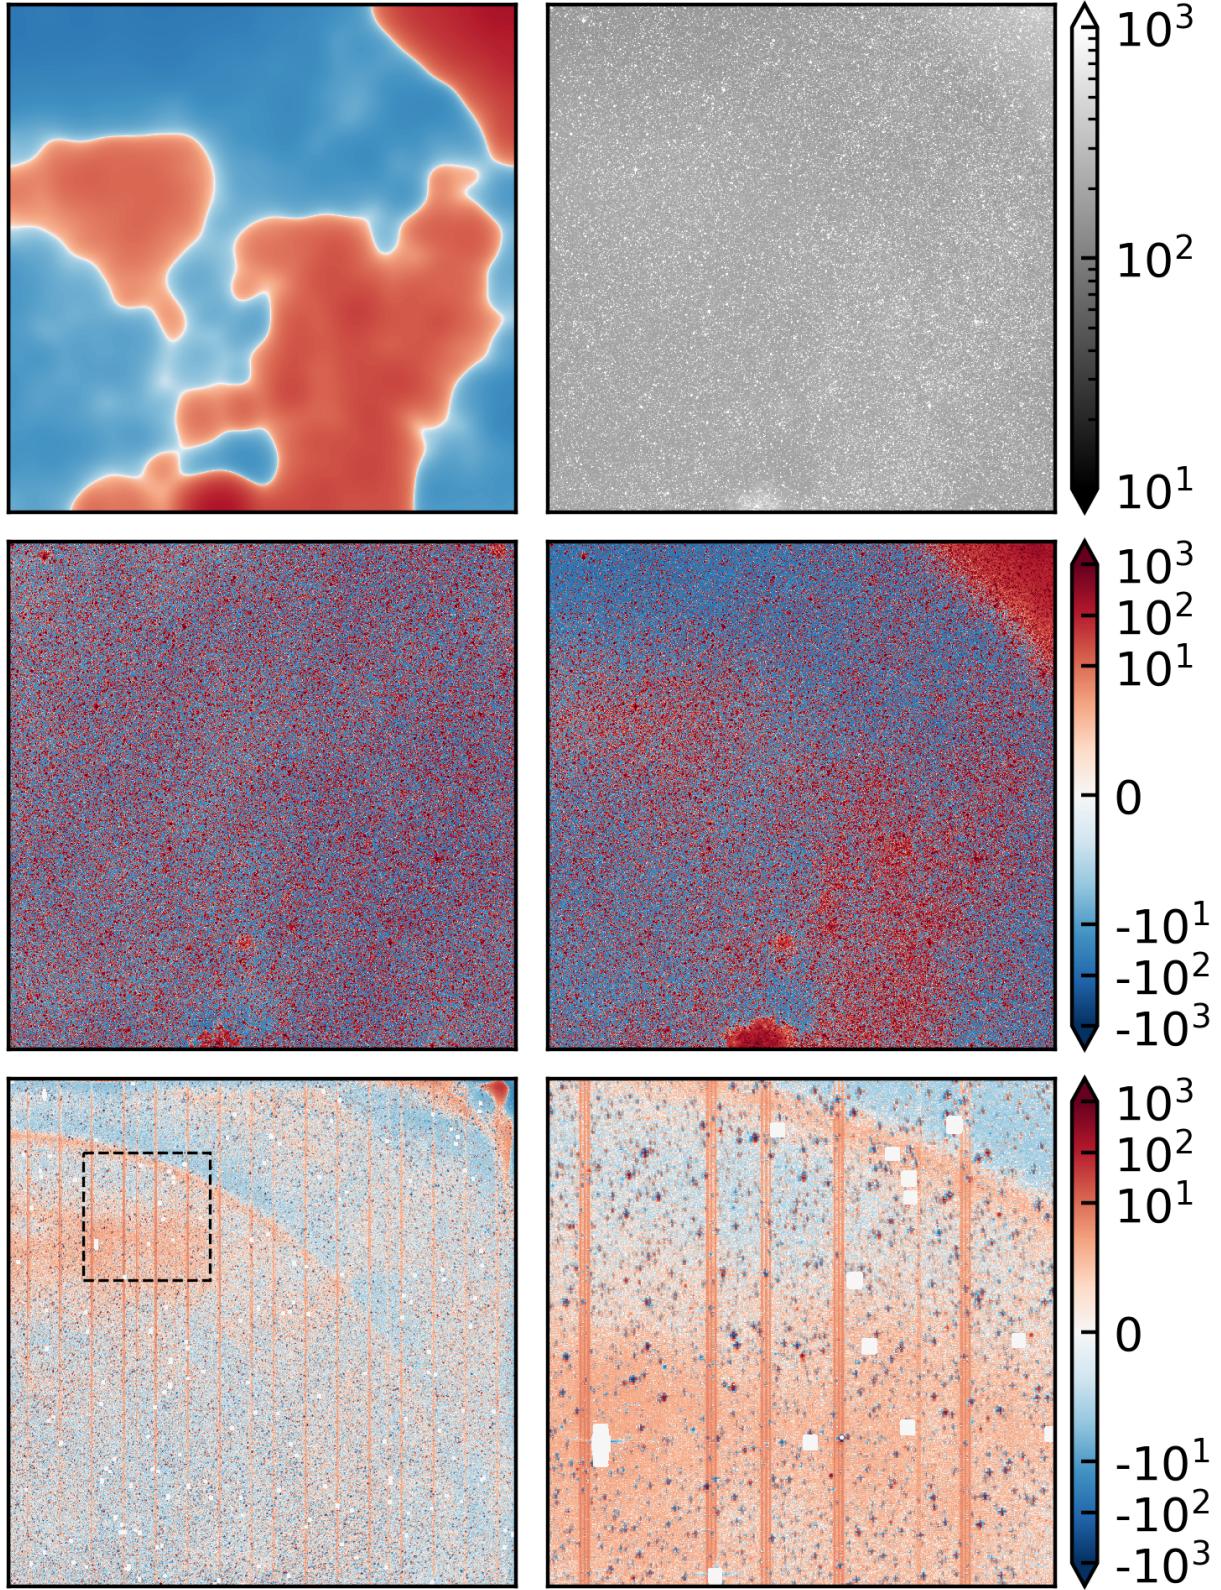

$$f(x, y) = B + A \exp\{-0.5 \times [s(\Delta x^2 + \Delta y^2) + d(\Delta x^2 - \Delta y^2) + k(2\Delta x\Delta y)]\}, \quad (1)$$

for  $(x_0, y_0)$  the central coordinates of the star,  $\Delta x = x - x_0$ ,  $\Delta y = y - y_0$ ,  $B$  the background level, and  $A$  an arbitrary flux-scaling constant. For a nearly circular shape profile, the sharpness  $s$  is related to the FWHM as  $\text{FWHM} \approx 2.35s^{-1/2}$  (*e.g.*, Pál 2009). These shape parameters are later used when selecting an astrometric reference frame (§ 3.5). In agreement with what is obvious upon visual inspection, this fitting process shows that stars closer to the center of each camera’s field are round, while stars near the field edges are more elongated.

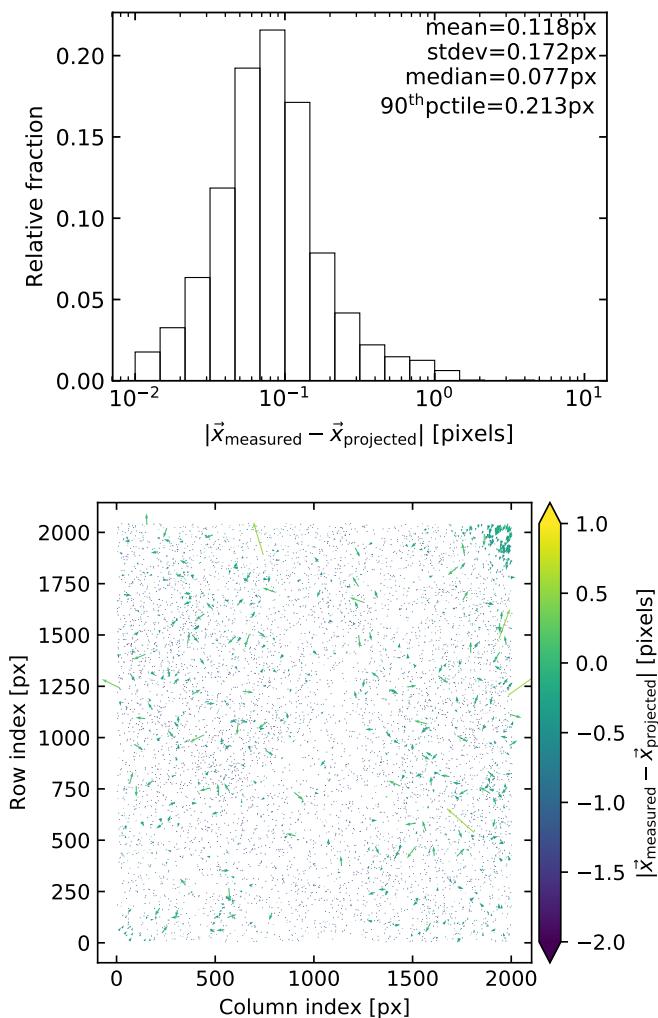

For the astrometric solution, we use the World Coordinate System (WCS) and fourth-order Simple Imaging Polynomial (SIP) coefficients derived by SPOC and included in the FFI headers (Pence et al. 2010, Sec. 8). We explored the possibility of using `astrometry.net` (Lang et al. 2010) to derive our own astrometric solutions for each frame, but found that the astrometric residual (the mean separation between projected and measured positions) was consistently a factor of 1.5–2 times higher in our WCS solutions than in those given by SPOC. This was perhaps because we did not develop a robust algorithm to select non-blended stars of intermediate brightness before measuring their positions.

With the resulting WCS information, we then project a source catalog onto each frame. We use the projected positions of the sources to center the apertures in our photometry, rather than attempting to measure the positions. Such “forced-aperture photometry” is preferable to source extraction in the crowded fields that are central to this work. The Gaia-DR2 epoch is J2015.5, so even the fastest-moving stars with proper motions of  $\sim 1 \text{ arcsecond yr}^{-1}$  are still well within one pixel of their predicted positions in the TESS images. The projection from catalog sky-coordinate positions to pixel coordinates is performed using an analog of the `wcs-rd2xy`

<sup>4</sup> [archive.stsci.edu/tess/tess\\_drn.html](http://archive.stsci.edu/tess/tess_drn.html), accessed 2019-08-12

**Figure 6.** Same sector, camera and CCD as Figure 5, but for an image obtained during perigee passage, when scattered light from the Earth is prominent. A number of systematic artifacts are present, including vertical “straps” and small-scale structure in scattered light patches. The quality of astrometric registration in the difference image is also worse, leading to larger residuals in the lower-right panel.

**Figure 7.** *Top.* Histogram of astrometric residual. The  $x$ -axis shows the distance between the measured centroid positions of stars, compared to the predicted positions from the WCS solution. *Bottom.* Vector plot of astrometric residual. Each arrow is the vector from the measured to the projected star position. Directions are correct, but lengths are 50 times their true size for visual clarity. The systematic error in the top-right corner is a typical problem generic to wide-field astrometry. The frame chosen for this plot is the photometric reference frame used for Sector 6, Camera 1, CCD 1; we automatically impose cutoffs on the median and 90<sup>th</sup> percentile of the astrometric residual in order to ensure similar levels of astrometric precision are maintained throughout the reduction.

program that performs the standard matrix algebra (Lang et al. 2010). The source catalog look-up is performed using `gaia2read`<sup>5</sup> (Kim 2018).

For the source catalog itself, we initially planned to photometer all Gaia-DR2 sources in each field down to a cutoff

<sup>5</sup> [github.com/samuelyewl/gaia2read](https://github.com/samuelyewl/gaia2read), commit 4b472d

of  $G_{Rp} < 16$ . However, for the galactic plane fields this produced an excessively large number of sources (millions of stars per  $12^\circ \times 12^\circ$  CCD). We therefore limited our source catalog for each frame to be a combination of the CDIPS target stars ( $G_{Rp} < 16$ ), and all Gaia-DR2 sources down to  $G_{Rp} < 13$ . The latter set of stars are used for image processing and light curve detrending.

Figure 7 displays the residual between the measured and projected stellar centroid positions for one photometric reference frame. The construction of this frame will be described shortly. The plot shows that the errors are typically largest in the corners of the image, where the non-linearity of the focal plane is most significant, and the corrections required by the SIP coefficients are largest. Also, the typical median precision of the WCS solution is a bit below 0.1 pixels, and its 90<sup>th</sup> percentile is typically less than 0.3 pixels. In our reduction, we therefore require that each frame’s median residual and 90th percentile remain below 0.2 and 0.4 pixels, respectively. If this constraint is not met, the reduction fails. This is an essential quality-control check for any forced-aperture photometry pipeline.

Finally, to collect the metadata needed to select photometric reference frames, we perform aperture photometry on the bright stars. This task is performed by using `fiphot` to sum the counts inside circular apertures centered on the projected stellar positions. The pixel weights are equal to the fraction of the pixel that falls within the circular aperture. They are unity for pixels entirely within the aperture, and fractional along the aperture boundary. The background levels are measured in annuli surrounding the center of each aperture.

### 3.5. Image subtraction

#### 3.5.1. Synopsis of image subtraction method

The core operation of “classical” image subtraction is to match a photometric reference image  $R$  and a target image  $I$  by computing and applying a convolution kernel. For ground-based data, this “match” typically corrects for differences in seeing or transparency between the reference and target; for space-based data, the match might correct for spacecraft jitter, or thermal and corresponding point-spread function (PSF) variations. The kernel, once applied to the high signal-to noise reference, produces a model image,  $M_{xy}$ ,

$$M_{xy} = (R \otimes K)_{xy} + B_{xy}, \quad (2)$$

where  $B_{xy}$  is a component of the model image that allows for background variations, and  $\otimes$  denotes convolution. Since we modeled the background separately (§ 3.3), we set  $B_{xy} = 0$ . The convolution kernel  $K$  is typically decomposed onto a basis,

$$K = \sum_i c_i K_i, \quad (3)$$

where the coefficients  $c_i$  are found by minimizing

$$\chi^2 = \sum_{xy} \left( \frac{I_{xy} - M_{xy}}{\sigma_{xy}} \right)^2, \quad (4)$$

for  $\sigma_{xy}$  the uncertainty in the target image pixel values. Photometry is then performed on the difference image  $D_{xy}$ , where  $D_{xy} = I_{xy} - M_{xy}$ . For the present reduction, the uncertainty in each target image pixel was taken to be a constant.

The general procedure described above was first proposed by Alard & Lupton (1998). It was reviewed and clarified by Miller et al. (2008). The choice of how to decompose the kernel was further explored by Bramich (2008), who showed that using a linear combination of delta functions (also called a “discrete kernel”) had advantages compared to a basis of gaussians. We perform the convolution using `ficonv`, and opt for the implementation of Bramich’s method (see Pál 2009 § 2.8). The lower panels of Figure 5 show the procedure working well, and producing a “clean” difference image. Figure 6 shows what happens for an image taken when scattered light from the Earth causes the model image to be a poor fit to the target image.

### 3.5.2. Astrometric registration

To make the above high-level picture work, we need to select two “reference frames”: (1) the astrometric reference frame; and (2) the photometric reference frame.

To choose the astrometric reference frame, we search for frames with compact, round stars (big  $s$ , small  $d$  and  $k$  values). We also require that the frame have a low background level, as measured in annuli around the bright stars selected in § 3.3. Finally, the astrometric reference frame needs to have a large number of detected sources (though the variance between TESS images was rather small). We sort the images using these metrics, and then select the astrometric reference frame from successive intersections of each sorted list.

We then compute and apply a spatial transformation to each calibrated frame in order to match the astrometric reference. This transformation – a combination of rotation, dilation, and translation – typically moves stars by less than a pixel, since the TESS spacecraft pointing is quite stable. We calculate the transformation using the measured source positions found in § 3.4, and the symmetric triangle point-matching scheme described by Pál (2009, § 2.5.2). This step is achieved using the `fitsh` tools `grmatch` and `grtrans`. To help ensure the precision of the transformation, we require the “unitarity”  $\Lambda$  (Pál 2009, Eq. 54), which characterizes the degree of distortion in the transformation matrix, to be below 0.01. To mitigate possible photometric errors incurred during this step, we also use the flux-conserving interpolation scheme described by Pál (2009), which is necessary because polynomial interpolation schemes do not conserve stellar flux.

### 3.5.3. Photometric reference frame construction & reference flux measurement

The second required reference frame is the photometric reference frame, which is used both to calculate the convolution kernel, and to obtain a reference flux for each star. To make it, we first choose 50 images with low background measurements (measured for each frame from the annuli around bright stars), and only consider frames with a relatively large

number of detected bright objects. We then convolve these candidate photometric reference frames to the frame with the lowest background measurement, and construct the photometric reference as the median image across the 50 frame stack.

Measuring the reference flux for each star is a non-trivial operation. First, we perform forced simple aperture photometry on the photometric reference frame to measure the flux for each source. The local background is estimated in annuli, with neighboring stars masked out during the background measurement. If we were to stop here, *it would be a mistake*. The reference fluxes for faint stars would be overestimated, due to crowding. The relative amplitude of photometric signals for faint stars would correspondingly be biased to lower values.

To avoid this problem, after performing simple aperture photometry on the reference frame, we fitted a line between the TESS T-band magnitude of the bright stars, and their measured fluxes. The TESS  $T$ -band magnitudes were calculated using the Gaia-DR2 magnitudes of each star, and Equation 1 of Stassun et al. (2019). We then used the known catalog magnitudes for all the stars on each image to predict the expected reference flux for each star. This accounts for crowding down to Gaia’s resolution limit of  $\approx 1''$ , rather than the TESS limit of  $\approx 20''$ .

The final instrumental flux values  $f$  we report are given by (Pál 2009, Equation 83)

$$f = f_{\text{reference}} + f_{\text{subtracted}} \quad (5)$$

$$= g(T_{\text{cat}}) + \frac{1}{||K||_1^2} \sum_{x,y} D_{xy} (w \otimes K)_{xy}. \quad (6)$$

The function  $g$  takes as input the target star’s catalog magnitude  $T_{\text{cat}}$ , and returns the reference flux. Its coefficients are found independently for each aperture. The difference image  $D$  is equal to  $I - (R \otimes K)$ , where as in Equation 2,  $I$  is the target image transformed to the astrometric reference,  $R$  is the photometric reference, and  $K$  is the convolution kernel. The weights  $w$  from the circular aperture mask are included in the convolution. The norm  $||K||_1$  is defined by Pál (2009) Equation 81.

### 3.6. Choice of convolution kernel

To solve for the coefficients  $c_i$  of the convolution kernel, a few further assumptions are necessary. The procedure implemented in `ficonv` is to subdivide the image, and within each grid element find the brightest non-saturated star. These isolated “stamp” stars are then used to solve for the coefficients of the kernel, by minimizing Equation 4 over the sum of all stamps. For the kernel basis, we use a linear combination of delta functions with a flux scaling term (Soares-Furtado et al. 2017 Section 3.3.1 gives the equations). In this model, spatial variations of the PSF across the image are captured by weighting each basis component with spatial polynomials up to a cut-off order.

This kernel model has three parameters that must be specified, but are not automatically optimized by the procedure:

(1) the box-size; (2) the maximum order of the polynomial weighting the delta function terms; (3) the maximum order of the polynomial weighting the flux scaling. We performed a grid-search to tune these parameters, in which our “loss functions” were the light curve standard deviation (RMS) as a function of magnitude, and the recovered SNR of transits from the catalog of known TOIs (TESS Objects of Interest; N. Guerrero, in preparation).

In the first dimension, we varied the kernel size between a box of  $3 \times 3$  pixels and  $11 \times 11$  pixels. Increasing the kernel box-size from a  $3 \times 3$  box to a  $7 \times 7$  box led to about a 50% lower light curve RMS for bright stars, and no difference for faint stars. The largest kernels, of  $(11 \times 11)$  pixels, returned slightly lower signal-to-noise for recovered transits than kernels of intermediate size. We settled on a kernel box-size of  $(7 \times 7)$  pixels, which is  $\approx 2$  times larger than the typical TESS FWHM at field center.

In the other two dimensions, we varied the spatial polynomial orders weighting the kernel’s individual pixels between first and fifth order. We did the same for the polynomial weights of the “identity” pixel. Varying the polynomial orders between 1 and 4 did not produce large differences. The fifth order polynomials retrieved transits with  $\approx 10\%$  worse SNR compared to lower order polynomials. We therefore adopted a second order polynomial weight in both terms.

Averaging over all TOIs present in the camera we used for these experiments, we found that different choices of kernel parameters produced variations of  $\lesssim 12\%$  in the retrieved transit SNR. For computational expediency, we therefore chose a single  $(7 \times 7)$  kernel with second-order spatial polynomial weights in the basis functions for the remainder of our reduction.

With a kernel selected, and the convolution and subtraction performed, we calculated the instrumental fluxes for each frame per Equation 6. We did this with three different aperture sizes: for this work, circles of radii 1 pixel, 1.5 pixels, and 2.25 pixels. These sizes were chosen to roughly span the range of optimal aperture sizes reported by Sullivan et al. (2015). Finally, to convert from a list of flux measurements for each source on a frame to light curves, we used the `fitsh` transposition tool `grcollect`.

### 3.7. Light curve detrending

The preceding steps produce light curves that include both instrumental systematics as well as astrophysical variability. Figure 8 shows twenty stars of comparable brightness randomly selected from two CCDs. Stars that are far apart on the same CCD often share similar changes in flux. In other words, the instrumental systematics seem to dominate. This problem is generic in wide-field photometric datasets, including the WASP, Kepler, and HAT surveys (Pollacco et al. 2006; Borucki et al. 2010; Bakos 2018). To remove the systematic variability, we adopted two different approaches: (*i*) the trend-filtering algorithm (TFA, Kovács et al. 2005), and (*ii*) a principal component analysis (PCA, see e.g., Ivezic et al. 2014 for a review).

However, a number of other approaches to the problem were possible. To encourage future improvements, we describe the possibility of decorrelating against external parameters (§ 3.7.1), and also different available approaches to ensemble detrending (§ 3.7.2), before explaining our adopted implementation.

#### 3.7.1. Decorrelating against external parameters

Often, ensemble trends of stellar magnitude with CCD position, sub-pixel position, catalog magnitude, and color are present in datasets. One detrending step that can be valuable is to fit and subtract a linear combination of these trends as they appear across many light curves (e.g., Zhang et al. 2016, § 5.5).

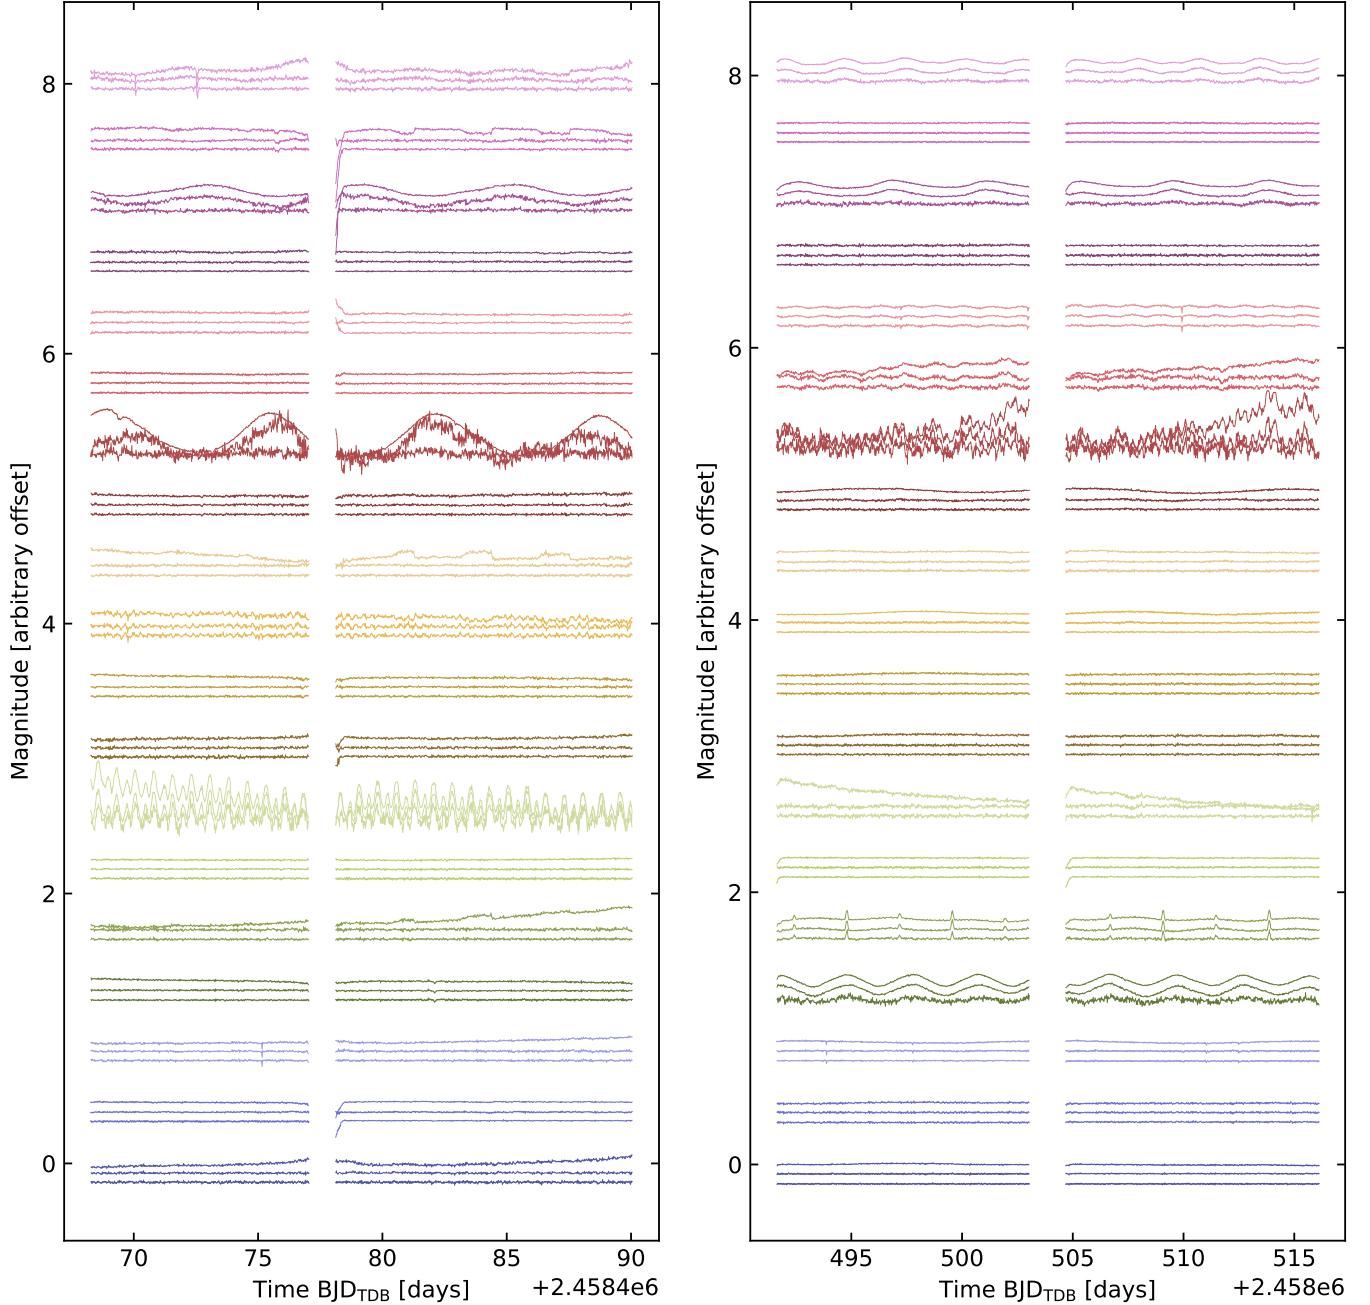

A separate step for each light curve can then be to fit out linear correlations of stellar magnitude with “external parameters” (EPD, Bakos et al. 2010; Huang et al. 2015). For ground-based data these parameters might include zenith angle, or changing PSF shape. For TESS data, they might include CCD temperature, or the angles of the Moon and Earth relative to each camera’s boresight. They might also include the standard deviation of the spacecraft quaternion time-series (Vanderburg et al. 2019). Some example “external” parameters that we include with our light curves are shown as functions of time in Figure 9.

We explored the possibility of fitting linear models of flux as functions of e.g., temperature, shape parameters, and centroid positions to each light curve. We also briefly explored non-linear model fitting using  $N$ -dimensional B-splines to fit the flux, centroid positions, and temperatures simultaneously (Dierckx 1996). The linear models typically under-fit the light curves, particularly during the large shifts that happen as the spacecraft nears perigee. The non-linear models showed some promise, but often seemed to overfit stellar variability signals. Given these complications, for the time being we omitted the step of “detrending” as a function of external parameters. To enable further exploration of the issue, we included all the necessary vectors of e.g., centroid positions, temperatures, and shape parameters in our reported light curves.

#### 3.7.2. Ensemble detrending

The parameters that capture systematic trends are often poorly known. In such cases, an effective model of the systematics comes from constructing a set of basis vectors that empirically captures trends common to many stars. Each target light curve is then assumed to be a linear combination of the trend vectors.

The well-known algorithms, TFA, Sys-Rem, PDC-MAP, and ARC2, all take slightly different approaches to constructing this set of basis vectors, as well as to solving for the weights to assign each linear component (Kovács et al. 2005; Tamuz et al. 2005; Smith et al. 2012; Aigrain et al. 2017). TFA selects individual “template stars” as basis vectors, and equally weights each template when solving for the coefficients via linear least squares. PDC-MAP computes “co-trending basis vectors” (CBVs) by applying singular value

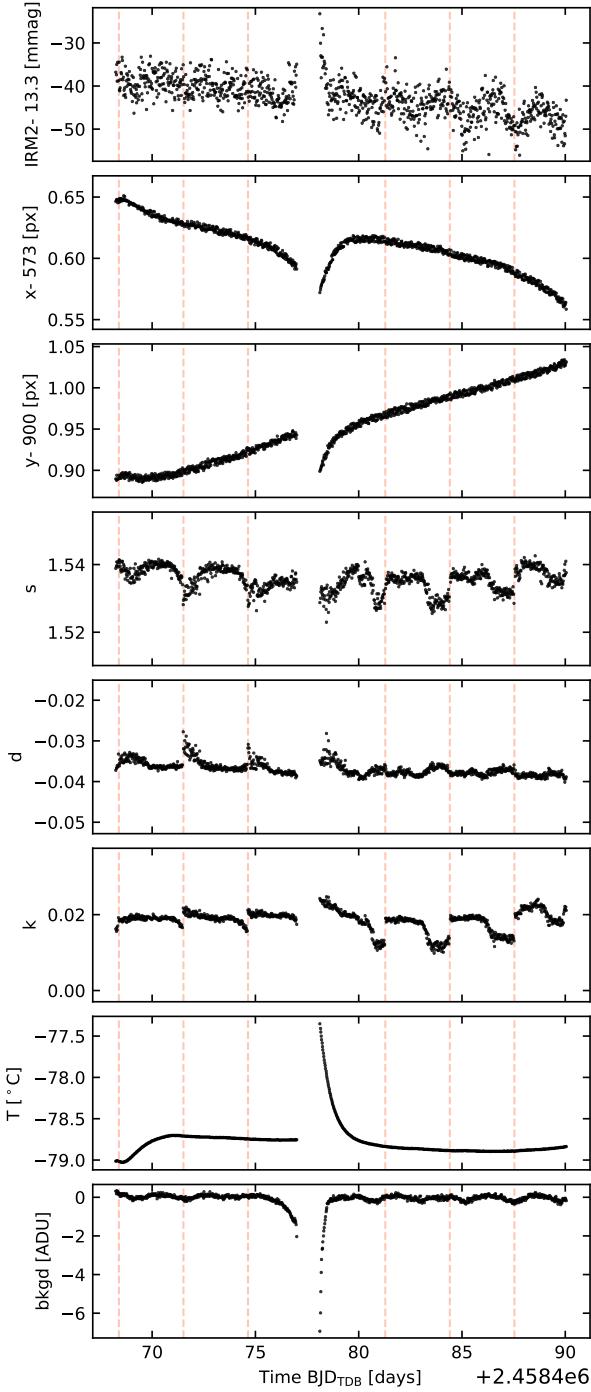

**Figure 8.** Twenty randomly selected light curves drawn from the same sector, camera, and CCD, for CDIPS target stars with  $T$ -band magnitudes between 13 and 14. For each star, we show the raw light curve (top), PCA-detrended light curve (middle), and TFA-detrended light curve (bottom). The sector, camera, and CCD numbers are 6, 1, 4 (left) and 7, 3, 2 (right). A number of systematic trends are shared across raw light curves (e.g., the periodic  $\sim 3$  day “chopping” seen in the left plot). In the PCA light curves, stellar rotation signals are usually preserved, but not always (e.g., left panel, seventh from the top). TFA filters out almost all long-term trends, or else heavily distorts them (e.g., right panel, fourth from the bottom)

decomposition to the light curves that show the strongest mutual correlation. It solves for the coefficients through a two-step procedure. The first step is to calculate the coefficients through linear least squares. The least-squares coefficients are then used to construct a prior over plausible coefficient values, which is subsequently used to recompute the max-

imum likelihood coefficients for each star. This latter step reduces overfitting for stars with variability not present in the set of CBVs.

We opted to use two different detrending approaches, each aimed at a different use case. For transit-search related science, we used TFA, as implemented in VARTOOLS (Kovács

**Figure 9.** The variability in flux is sometimes correlated with variability in “external” parameters, shown here for a representative star over two orbits. *Top:* Instrumental raw magnitude (with a particular aperture size), as a function of time. Continuing in order are  $x$  and  $y$  centroid positions as functions of time, the  $(s, d, k)$  PSF shape parameters, the CCD temperature, and the measured background value. Differential aberration affects the centroid position over the span of each orbit. Momentum dumps are marked with vertical dashed lines, and affect the measured shapes of stars.

et al. 2005; Hartman & Bakos 2016). For stellar astrophysics related work, we used a simple variant of PCA, as implemented in `scikit-learn` (Pedregosa et al. 2011). For self-consistency, we describe each method and its implementation in the following paragraphs.

**TFA detrending**—The idea of TFA is as follows. Suppose we have  $M$  “template stars”, which are a subsample of stars that represent all types of systematics across the dataset. Each template star has a light curve with  $N$  data points. Denote the template time-series  $X_j(i)$ , where  $j = 1, \dots, M$  and  $i = 1, \dots, N$  is the time index. We then want to find periodic signals in a target time-series  $Y(i)$ . This is done by defining a filter function

$$F(i) = \sum_{j=1}^M c_j X_j(i), \quad (7)$$

for which the coefficients  $c_j$  are found by minimizing

$$\mathcal{D} = \sum_{i=1}^N [Y(i) - A(i) - F(i)]^2. \quad (8)$$

When trying to find periodic signals,  $A(i)$  represents our prior knowledge of the light curve’s shape. Initially, this prior is simply that stars on average maintain a constant brightness:

$$A(i) = \langle Y \rangle = \frac{1}{N} \sum_{i=1}^N Y(i) = \text{const.} \quad (9)$$

If a signal is eventually found, for instance using the box-least squares method (Kovács et al. 2002), this detrending process must then be repeated while accounting for our updated knowledge about the light curve’s shape.

Some implementation notes follow. We selected template stars in two stages. In the first stage, we fitted a parabola in the RMS-magnitude plane, and discarded stars more than  $2\sigma$  away from the prediction of the fit. We also required that these initial candidate stars have intermediate brightness ( $8.5 > T > 13$ ), and have a relatively large number of time-series data points. We excluded templates within 20 pixels of any given target star. We then performed an initial iteration of TFA, on only the candidate template stars. We inspected the resulting detrended light curves for residual structure by computing a Lomb-Scargle periodogram. If the maximum-power peak had a false alarm probability below 0.1%, we excluded the star from the list of candidate template stars, on the basis of its presumed periodic variability. We then randomly selected at most 200 template stars from the remaining non-variable candidates. The choice of number of template stars was discussed by Kovács et al. (2005), and is another free parameter in the broad problem of light curve production. This choice is analogous to the issue of how many cotrending basis vectors to choose in PDC-MAP or ARC2 (Aigrain et al. 2017). While the number of template stars can be optimized by constructing and minimizing a BIC-like quantity, a little overfitting is acceptable for our purpose of finding planetary transits. For other applications, e.g., stellar

rotation period searches, it is almost certainly preferable to adopt a less forceful detrending approach.

**PCA detrending**—To remove the largest systematic trends with minimal overfitting of *e.g.*, stellar rotation signals, we adopted a simple variant of PCA. A similar approach was taken by [Feinstein et al. \(2019\)](#) in `eleanor`. We derived the principal components for each CCD using the 200 template stars previously selected for TFA. We then modelled each target light curve as a linear combination of a subset of these principal components, and determined the weights via linear least squares. Both steps were performed using `scikit-learn` ([Pedregosa et al. 2011](#)).

To determine the number of principal components at which to truncate the model, we performed a cross-validation analysis. Again, this was achieved using `scikit-learn`. As is typically the case when the noise variance is different for each “feature” (each point in time), we found that  $k$ -folding cross-validation of the PCA components gave a cross-validation score that monotonically increased with an increasing number of components<sup>6</sup>. We found that if we instead performed a factor analysis, the cross-validation score was typically maximized with anywhere from 10 to 15 components. This agreed with a visual analysis of the number of PCA components past which overfitting began. We therefore used the maximum cross-validation score from the factor analysis as the number of principal components to use in each light curve. This number is documented in the FITS header of each light curve.

While the PCA detrending should help remove the most egregious systematic artifacts, it remains possible that PCA can distort signals, and even inject correlated noise into a light curve (*e.g.*, Figure 8). For any object of interest, it is worth inspecting the raw, PCA, and TFA light curves to ensure that the variability of interest is not adversely affected by the detrending procedures. If it is, alternative approaches may be necessary.

## 4. RESULTS

### 4.1. Light curve statistics

#### 4.1.1. Stellar properties

Figure 10 shows the on-sky locations of the light curves from Sectors 6 and 7. Black points are the field stars for which we performed photometry in order to construct basis vector sets for TFA and PCA. Blue points are the 159,343 target stars for which light curves are available at [archive.stsci.edu/prepds/cdips](#). Most of the target stars are close to the galactic plane, and are spatially clustered. Gaps between CCD chips are also visible.

Figure 11 shows the cumulative distribution of TESS  $T$ -band magnitudes for the target stars. Though most of the targets are faint,  $\approx 3 \times 10^4$  are brighter than  $T = 13$ . The

brighter targets will be more amenable to detailed spectroscopic observations, should the need arise.

An HR diagram for the entire sample of CDIPS stars on silicon is shown in Figure 12 (top). The sub-sample of stars with measured positive parallaxes and naive distances less than 1 kpc is also shown (bottom). About one-third of the stars are in this latter sample. Of the close stars, a relatively large fraction come from [Zari et al. \(2018\)](#), and are either on the PMS or upper main-sequence. The latter set of OBA dwarf stars, while “younger” than the typical field dwarf, are the least interesting subset of our target sample from the perspective of age analyses. In the entire sample (Figure 12 top), a much larger fraction of stars are sub-giants, red giants, and helium-burning red-clump stars.

Finally, Figure 13 shows the proper motions of the entire and close samples of stars on silicon. Each clump signifies a different star cluster. The large overdensity in the top panel is composed mainly of field star contaminants. It has two sub-components, due to the two different directions in the Galaxy being observed in Sectors 6 and 7.

#### 4.1.2. Cluster membership provenance

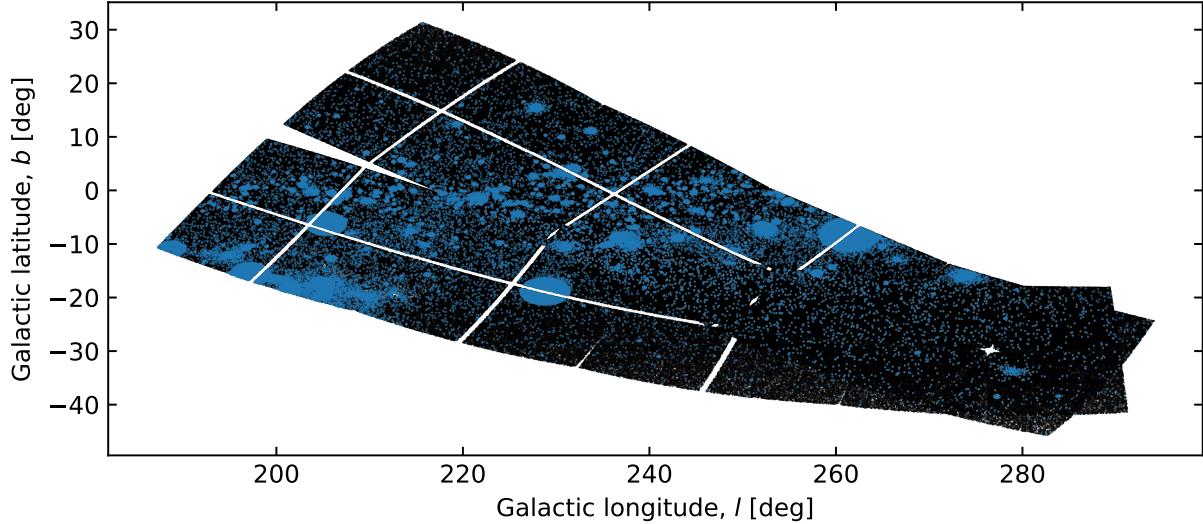

**Sector 6**—In Sector 6, 67,612 light curves of candidate cluster stars were made. The provenance of the target star for these sources is [Dias et al. \(2014\)](#) for 40% of the sources; [Zari et al. \(2018\)](#) for 11% of sources from their upper main-sequence table and 7% of sources from their PMS table; [Kharchenko et al. \(2013\)](#) for 18% of sources; [Cantat-Gaudin et al. \(2018\)](#) for 14% of sources; and more than two catalogs for the remaining 10% of sources.

Table 2 lists the clusters in Sector 6 with the largest numbers of light curves. The top four clusters are all moving groups or stellar associations from [Dias et al. \(2014\)](#): Platais 5, Platais 6, Mamajek 3, and Collinder 70. These membership claims should be regarded with skepticism. For Platais 6, [Kharchenko et al. \(2013\)](#) claimed only about 400 probable members ( $1\sigma$ ) to exist within the angular radius of the cluster. Mamajek 3 (= 32Ori) similarly has only about 50 confirmed members ([Bell et al. 2017](#)). Some rich open clusters in the Sector 6 field with both many light curves and more reliable membership lists include Trumpler 5, Collinder 69 (the  $\lambda$  Orionis cluster), and NGC 2287.

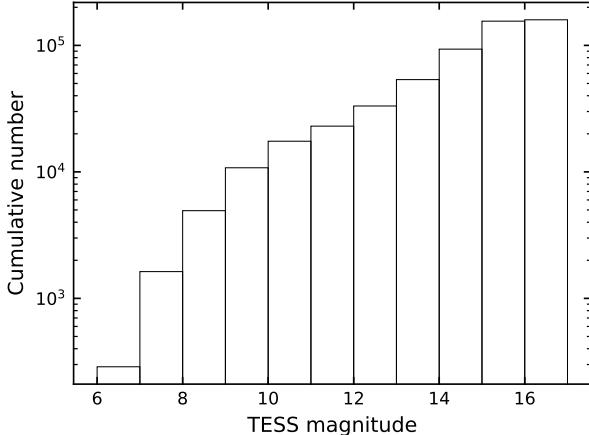

**Sector 7**—In Sector 7, 91,731 light curves of candidate cluster stars were made. The provenance of the claimed cluster origin of these sources is [Dias et al. \(2014\)](#) for 28% of the sources; [Kharchenko et al. \(2013\)](#) for 24% of sources; [Zari et al. \(2018\)](#) for 8% of sources from their upper main-sequence table and 3% of sources from their PMS table; [Cantat-Gaudin et al. \(2018\)](#) for 22% of sources, and more than two catalogs for the remaining 15% of sources.

Table 3 shows the clusters from Sector 7 with the largest number of light curves. Many rich open clusters, including NGC 2437, 2477, 2546, and 2451 are in the field. The cluster listed with the most light curves is the Collinder 173 association, chiefly due to the [Dias et al. \(2014\)](#) memberships. [Kharchenko et al. \(2013\)](#) note Collinder 173 as being coinci-

<sup>6</sup> See for example [https://scikit-learn.org/stable/auto\\_examples/decomposition/plot\\_pca\\_vs\\_fa\\_model\\_selection.html](https://scikit-learn.org/stable/auto_examples/decomposition/plot_pca_vs_fa_model_selection.html), accessed 2019-08-06.

**Figure 10.** Positions of light curves from TESS Sectors 6 and 7 in galactic coordinates. Black:  $G_{Rp} < 13$  field stars. Blue:  $G_{Rp} < 16$  target stars. Target stars are mostly near the galactic plane. The data for Sectors 6 and 7 cover about one-sixth of the galactic plane.

**Figure 11.** Cumulative number of CDIPS light curves a function of TESS  $T$ -band magnitude. Light curves were made for the target stars (Figure 2) that were observed in Sectors 6 or 7.

dent with the Vela OB2 association, and hence they flag it as a “duplicate”. Along with Sco-Cen and the Orion star forming complex, the Vela OB2 association is one of the largest young associations within 500 pc (Zari et al. 2018). Crucially though, Cantat-Gaudin et al. (2019a) recently studied the region using Gaia DR2 astrometry, and found that they could subdivide the complex into seven distinct stellar populations, with a total of  $\sim 11,000$  members. None of these populations map one-to-one to the classic labels of “Collinder 173” or “Vela OB2” – so the Cantat-Gaudin et al. (2019a) catalog is likely a more reliable source of information for this particular region of the sky.

#### 4.1.3. Light curve noise properties

*Observed RMS vs magnitude.*—Figure 14 shows the standard deviation of the TFA-detrended light curves as a function of the catalog  $T$ -band magnitude for CDIPS target stars. For the

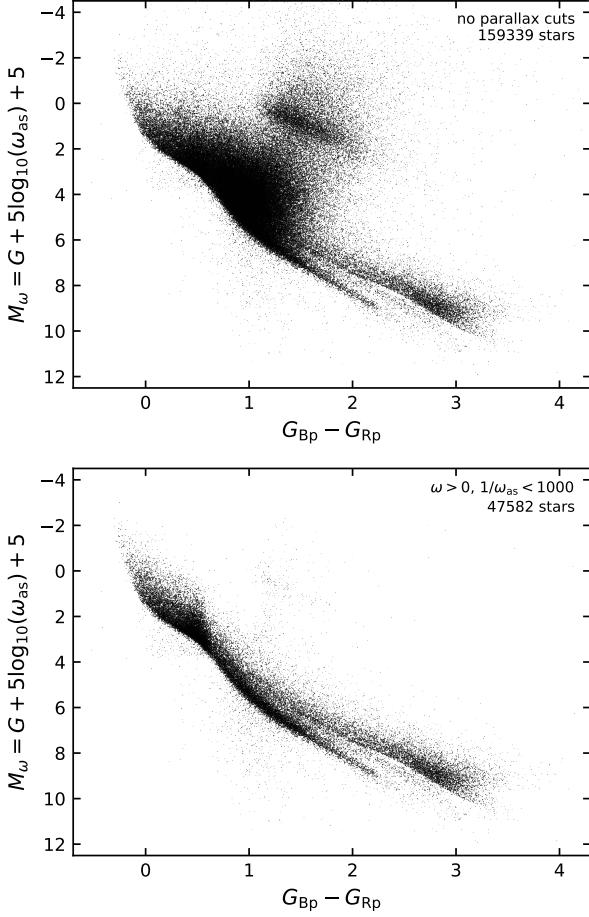

y-axis of this plot, we have taken

$$\text{RMS} = \left[ \frac{1}{N-M-1} \sum_{i=1}^N (f_i - \bar{f})^2 \right]^{1/2}, \quad (10)$$

where  $f_i$  is the value of the flux at the  $i^{\text{th}}$  point in the time-series,  $\bar{f}$  is the mean flux,  $N$  is the number of points in the time-series, and  $M$  is the number of template light curves (principal components) used during TFA (PCA) detrending. The correction in the denominator is for the overfitting inherent in any ensemble detrending method.

The observed RMS (black points) follows the usual shape, with source photon noise dominating from  $T = 9$  to  $T = 12$ , beyond which the onset of the “sky” background changes the overall slope of the curve to be more steep. For the brightest stars ( $T \lesssim 9$ ), a “systematic floor” of  $60 \text{ ppm} \text{ hr}^{1/2}$  was part of the mission’s error budget (Ricker et al. 2015), but has not been observed in early reports of the photometric performance of various aperture photometry pipelines (e.g., the SPOC pipeline Jenkins et al. 2010, the MIT-QLP Huang et al. 2018, and eleanor Feinstein et al. 2019). The fact that our light curves for the brightest stars are above this purported “floor”, rather than below it, suggests that our image subtraction techniques could be introducing some small degree of noise to the light curves of the brightest stars. It is also true however that our largest aperture contains only about 16 pixels, which is sub-optimal for stars brighter than  $T \approx 9$  (Sullivan et al. 2015, Figure 14). Since the brightest stars are not the focus of the present work, we leave this issue unaddressed for the time being.

An essential feature of our RMS diagram is that faint stars in crowded regions are not spuriously driven below theoretical limits. In aperture photometry pipelines, a star in a crowded region has its reference flux overestimated relative to the true number of photons it contributes (due to contamination from neighbor stars). As a result, changes in relative

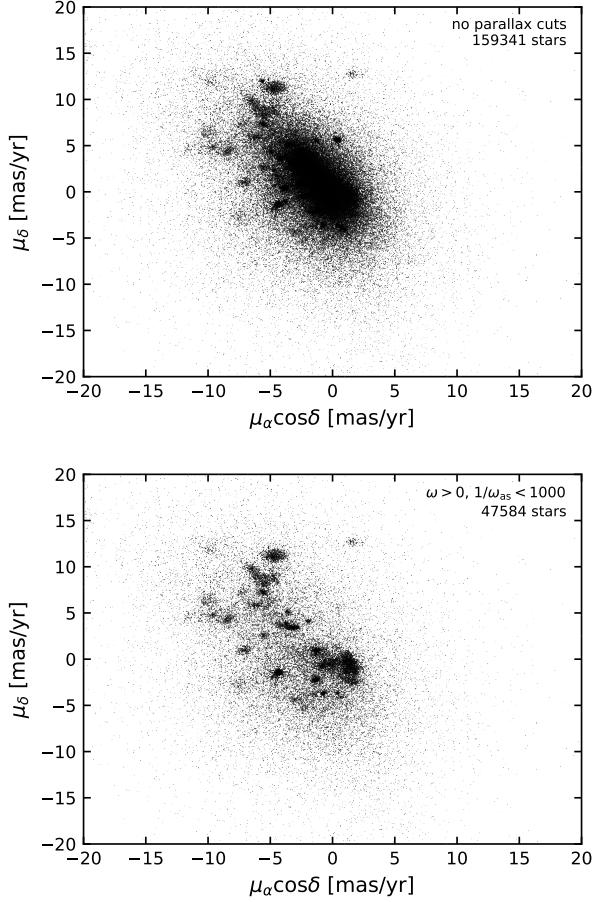

**Figure 12.** *Top.* HR diagram of CDIPS stars on silicon in this data release. *Bottom.* HR diagram of close CDIPS stars on silicon. The wedge separating the pre-MS sample from the MS stars was discussed by Zari et al. (2018), who introduced it in order to avoid contamination by photometric binaries.

flux in the faint star’s light curve are underestimated, and its RMS is driven low (*e.g.*, the faint end of Feinstein et al. 2019, Figure 5). Our method to work around this issue – using the catalog magnitudes to predict the reference flux values, and measuring deviations from these reference fluxes on the subtracted images – seems to be performing as intended.

*Expected RMS vs magnitude.*—The noise model shown in Figure 14 is quite similar to that of Sullivan et al. (2015), save for two changes. The first change is that the effective area of the telescope is updated to be  $86.6\text{cm}^2$ , per the measurements by Vanderspek et al. (2018).

The second change is that we have explicitly included the estimated noise contribution from unresolved faint stars. The brightness of the diffuse sky is dominated by different sources at different wavelengths. For instance, the CMB is most important in the microwave, and thermal radiation from dust grains in the solar system (zodiacal light) is dominant in the far infra-red (Leinert et al. 1998). In the TESS-band,

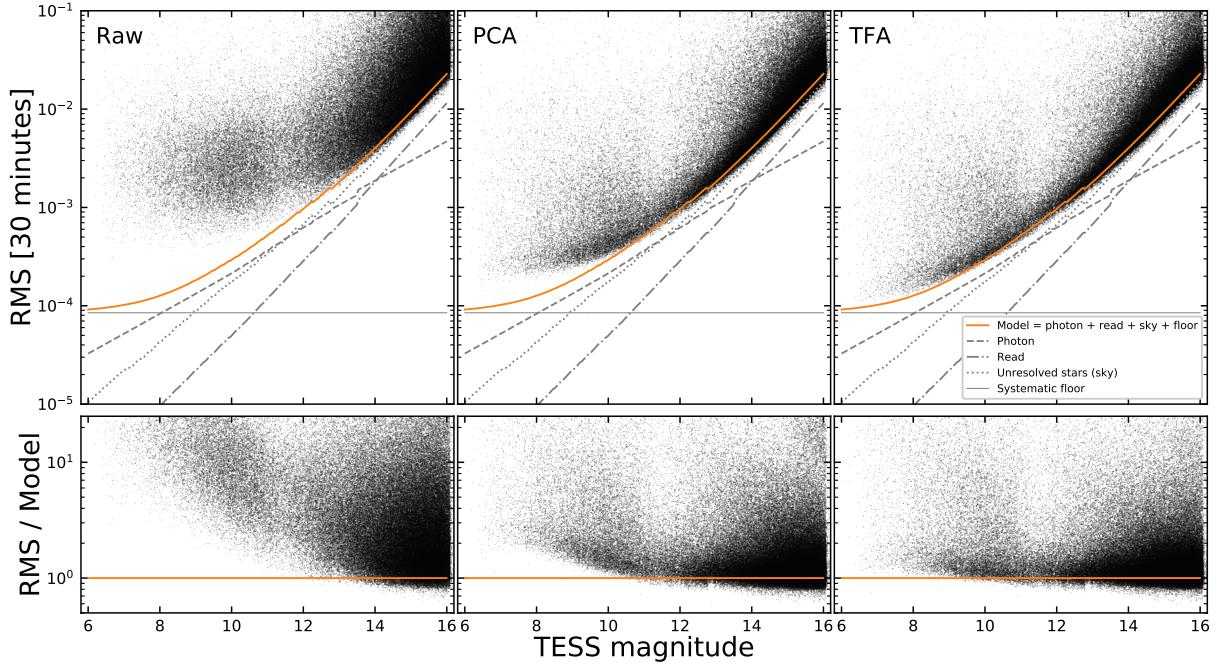

**Figure 13.** *Top.* Proper motions of CDIPS stars on silicon in this data release. Many of the stars in the central “blob” are possible field-contaminants. *Bottom.* Proper motions of close CDIPS stars on silicon.

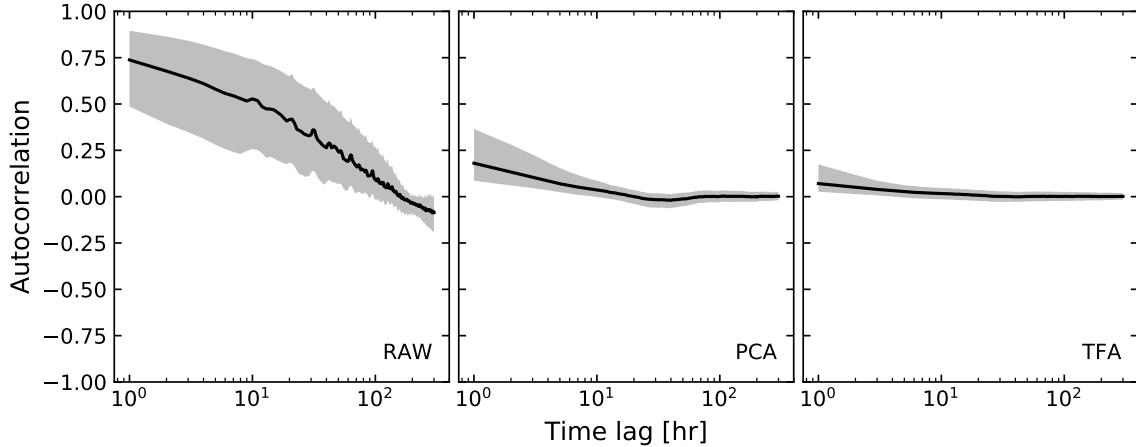

both zodiacal light and faint stars can play a role, depending on the line of sight under consideration. The zodiacal light is brightest near the ecliptic plane, and the faint star background is brightest near the galactic plane. When performing pre-launch noise estimates, Winn (2013) estimated the photon-counts from each component. His zodiacal light model was presented by Sullivan et al. (2015), but the faint star component was not emphasized since the Sullivan simulations were performed for fields away from the galactic plane.

The diffuse sky model we have used for Figure 14 is adopted explicitly because most of our target stars are near the galactic plane. Stars are judged to be “unresolved” and part of the background if their surface density exceeds the angular resolution of  $\Delta\theta \sim 1'$ , set by a combination of the pixel size as well as the typical stellar FWHM. Sources with sky surface density exceeding  $\Delta\theta^{-2}$  therefore contribute to the background.

The relevant quantity needed to calculate the integrated photon counts from faint sources is  $N(< m, l, b)$  — the num-

**Figure 14.** Standard deviation of CDIPS light curves as a function of catalog TESS-band magnitude. Left-to-right are raw, PCA-detrended, and TFA-detrended light curves. Black points correspond to the minimum RMS across the three available aperture sizes. The model (orange and gray lines) assumes aperture sizes calculated by Sullivan et al. (2015), and the effective area from Vanderspek et al. (2018). The noise from unresolved background stars (dotted gray line) is a function of galactic latitude, and dominates over zodiacal light for faint stars near the galactic plane; the line shown assumes a sight-line towards the center of Sector 6, Camera 1 (further details are in § 4.1.3).

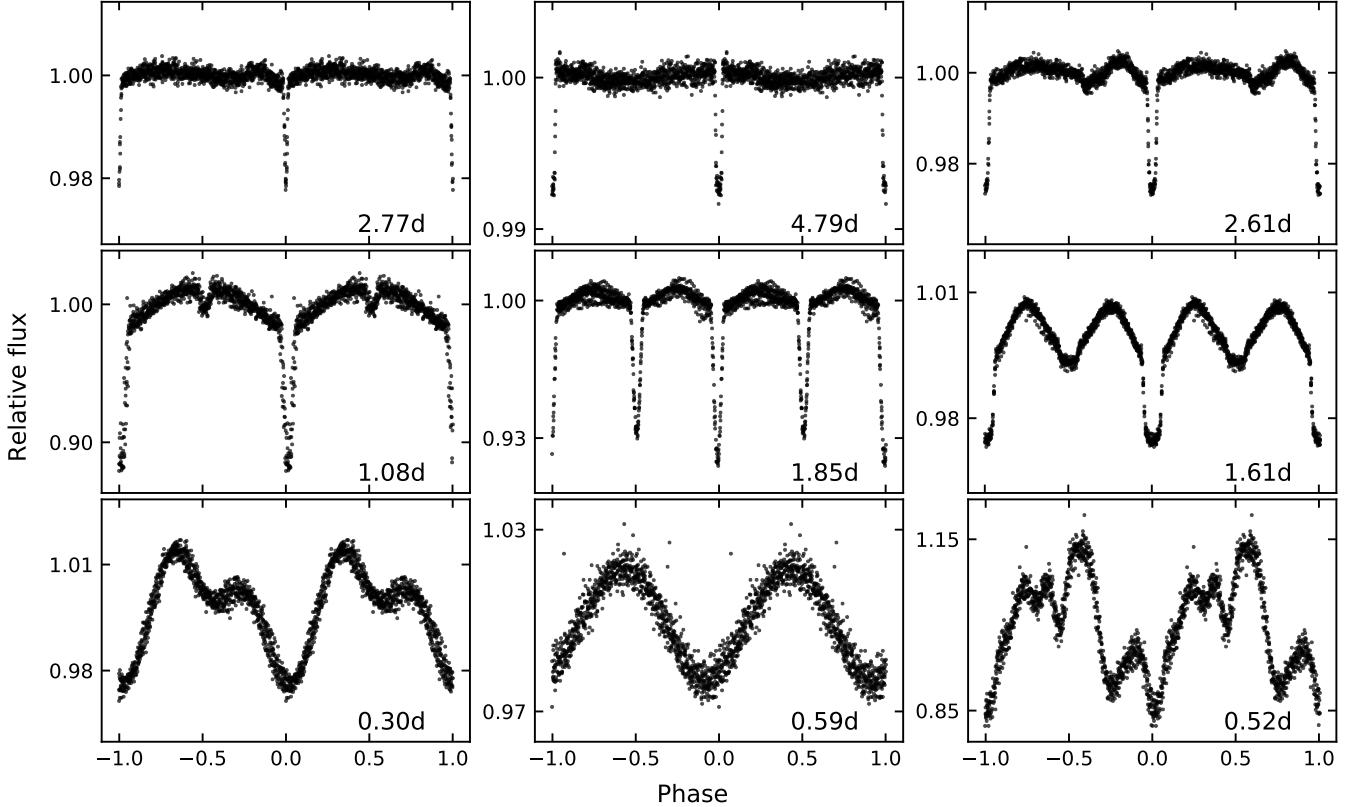

**Figure 15.** Average autocorrelations of  $10^4$  randomly selected light curves from each sector. The medians at time lags spaced by one hour are shown for raw light curves (column name `IRM`) in gray, and for TFA-detrended light curves in black. The gray bands display the 25<sup>th</sup> to 75<sup>th</sup> percentile range for each type of light curve.

ber of stars per square arcsecond brighter than magnitude  $m$ , along a line of sight with galactic longitude and latitude  $(l, b)$ . To calculate this surface density, Winn (2013) queried the Besançon model (Robin et al. 2003) along a grid of galactic sight-lines, and then converted to  $I$ -band surface brightnesses. Fitting a smooth function to the results, Winn (2013) found

$$I \text{ mag arcsec}^{-2} = a_0 + a_1 \left( \frac{|b|}{40^\circ} \right) + a_2 \left( \frac{|l|}{180^\circ} \right)^{a_3}, \quad (11)$$

where the galactic longitude  $l$  is measured from  $-180^\circ$  to  $180^\circ$ , and the empirical coefficients were found to be  $a_0 = 18.9733$ ,  $a_1 = 8.833$ ,  $a_2 = 4.007$ , and  $a_3 = 0.805$ . The model is *very approximate*. It is sensitive to the threshold used to select “unresolved” stars, and likely no more accurate than 0.5 mag on average. In regions with exceptionally high extinction (*e.g.*, star forming regions) it is expected to systematically underestimate the background brightness by an even larger degree. Nonetheless, this model for the diffuse sky back-

**Figure 16.** Phased PCA light curves for a few objects of interest. *Top row, left to right:* TOI 496 in Messier 48; TOI 625 orbiting a late A dwarf; and an eccentric EB in Bochum 5. *Middle row, left to right:* A detached EB in a 80 Myr old cluster; V684 Mon (a 10 Myr old detached EB); and a semi-detached EB in NGC 2548. *Bottom row, left to right:* Spotted rotator in NGC 2184; V468 Ori, a flaring M dwarf in Messier 42 with a strong rotation signal; Rapidly rotating 30 Myr old M dwarf, similar to those described by Zhan et al. (2019). Gaia source identifiers are given in the text.

ground seems to agree reasonably well with the observed trend of standard deviation versus stellar magnitude.

**ACF statistics**—Beyond the white noise properties of the light curves, the red noise properties are also important. In Figure 15 we show the average autocorrelation of the raw, PCA, and TFA light curves. The raw light curves have substantial red noise, and their average autocorrelation across many time lags is positive. The PCA and TFA light curves are much closer to white noise – the average autocorrelation between any two points in these light curves is close to zero. However, the average PCA and TFA light curves are not *completely* uncorrelated. At time lags of a few hours or less, there is some excess power. This suggests that additional detrending may be necessary to maximize the effectiveness of planet searches, or the discovery of any other signals via matched-filter techniques.

#### 4.2. Exploring the variability

The light curves provide an opportunity to study many types of variables, including pulsating stars, rotators, eclipsing binaries, and transiting planets. A few hand-picked ex-

amples are shown in Figure 16. The sources<sup>7</sup> were identified by calculating Lomb-Scargle and transit-least squares periodograms for a subset of the light curves, and inspecting the peaks with the greatest power (Lomb 1976; Scargle 1982; Kovács et al. 2002; VanderPlas & Ivezić 2015; Hippke & Heller 2019). We calculated the periodograms using astrobase (Bhatti et al. 2018). Our search was cursory – a detailed search for transiting exoplanets will be the subject of future work. To make the figure, we used the “PCA2” light curve for each star. To remove outliers, we omitted data points within 6 hours of the beginning or end of each orbit. No additional detrending was performed.

The top row of Figure 16 shows two TESS objects of interest, and an eccentric eclipsing binary. TOI 496 is a member of Messier 48 (NGC 2548, Gaia Collaboration et al. 2018b; Cantat-Gaudin et al. 2018), a ~500 Myr old open cluster (Kharchenko et al. 2013). The phase variations suggest that it is an eclipsing binary. TOI 625 is a potential hot Jupiter orbiting an upper main sequence star, and was included as

<sup>7</sup> Top-left to bottom-right: 3064530810048196352, 3080104185367102592, 3027361888196408832, 3125738423345810048, 3326715714242517248, 3064487241899832832, 3024952755135530496, 3209428644243836928, 3214130293403123712

a CDIPS target through the [Zari et al. \(2018\)](#) catalog. The eccentric EB was claimed by [Dias et al. \(2014\)](#) to be a member of the  $\sim 50$  Myr Bochum 5 cluster. This EB is also notable because its TFA light curve heavily whitens the out-of-eclipse signal, leaving an eclipse signal that could be mistaken for a planet candidate. The relevant lesson for anyone using the light curves is to verify that detrending does not introduce or remove signals that alter the interpretation of the system.

The middle row of Figure 16 shows a few more interesting eclipsing binaries. On the left is a detached EB exhibiting large out-of-eclipse modulations in a  $\sim 80$  Myr open cluster (“vdBergh 85”, [Kharchenko et al. 2013](#)). In the middle we have V684 Mon, a well-known  $\sim 10$  Myr old detached EB in the very young star-forming region NGC 2264. Finally on the right, we have a semi-detached EB in Messier 48.

The bottom row of Figure 16 gives a few examples of rotational variables. On the left, a spotted rotator in the  $\sim 400$  Myr NGC 2184 ([Cantat-Gaudin et al. 2018](#)). In the middle we have V468 Ori, a flaring M dwarf in Messier 42 with a strong rotation signal. Finally on the right is a  $\sim 30$  Myr old M dwarf in ASCC 19 with complex rotational modulation. The star was also flagged by [Zari et al. \(2018\)](#) as a pre-MS star. Similar modulations were described by [Zhan et al. \(2019\)](#) for rapidly rotating M dwarfs in other moving groups, and were suggested to be caused by star spot occultations behind a protostellar disk.

Overall, our periodogram search showed that 7% of the light curves have Lomb-Scargle peak false alarm probabilities below  $10^{-30}$ . Even more stars are variable at lower levels of significance. This implies that thousands of variable stars with known ages should be identifiable from the data at their current level of preparation.

## 5. DISCUSSION & CONCLUSION

In this study, we collected an all-sky sample of about one million stars brighter than 16<sup>th</sup> magnitude in  $G_{\text{Rp}}$ . 82% of these target stars are candidate “cluster” members, where we use the generic “cluster” to refer to open clusters, stellar associations, and moving groups. The remaining stars have photometric or astrometric indications of their youth, and either reside on the pre-main-sequence or upper main sequence.

We then reduced TESS full frame images taken over the course of about two months (Sectors 6 and 7; the first fields close to the galactic plane). We performed difference imaging to deal with the complex background. Using forced aperture photometry, we made light curves for all Gaia-DR2 sources brighter than  $G_{\text{Rp}}$  of 13, and went three magnitudes deeper for our target star sample. This yielded 159,343 target star light curves across 596 distinct clusters. The number of light curves per cluster was reported (Tables 2 and 3). The software developed for the reduction is available online ([Bhatti et al. 2019](#)).

The light curves seem to be limited in precision by photon-counting noise from the target star at the bright end, and by unresolved background stars at the faint end (Figure 14). Though the raw light curves show significant red noise,

decorrelating against a set of template stars led to an ensemble of light curves with very nearly white noise properties (Figures 8 and 15).

Brief exploration of the data revealed pulsating stars, eclipsing binaries, and planet candidates (Figure 16). A detailed planet search is the subject of ongoing work.

We expect that our results will complement a number of other TESS data processing efforts. These include the NASA Ames SPOC pipeline ([Jenkins et al. 2010](#)), the MIT Quick-Look-Pipeline ([Huang et al. 2018](#)), [eleanor](#) ([Feinstein et al. 2019](#)), the [Oelkers & Stassun \(2018\)](#) difference imaging pipeline, the TESS Asteroseismic Consortium (TASOC) pipeline ([Lund et al. 2015; Handberg et al. 2019](#)), and the Padova team’s effort (D. Nardiello, submitted; *e.g.*, [Libralato et al. 2016](#)).

Most of these pipelines are geared towards tasks more general than our own, and most use aperture photometry. The SPOC pipeline produces the calibrated FFIs from raw images, processes 2 minute data, identifies exoplanets, and produces the TESS data products of record. The MIT-QLP processes a subset of stars on the FFIs, identifies exoplanets, and the affiliated TESS Science Office alerts object of interest for ground and space-based followup. The [eleanor](#) pipeline is a user-friendly tool for extracting light curves from the FFIs. The team developing [eleanor](#) is also reporting planet candidates to ExoFOP-TESS<sup>8</sup>. The TASOC pipeline is primarily aimed at asteroseismology and includes classification modules for many types of variable stars. The [Oelkers & Stassun](#) pipeline was aimed at broad, all-sky variability searches, and used difference imaging methods similar to our own. Finally, the Padova team’s effort is also directed towards star clusters, but uses PSF subtraction to mitigate crowding. As light curves from these groups continue to be released, this ecosystem should provide many opportunities to compare and improve data analysis techniques.

There are of course caveats and areas for improvement in our own work. One methodological point concerns the hyperparameter tuning required by our difference imaging method (§ 3.6). Within our fine-tuning experiments over different kernel box-sizes and polynomial weightings, we found that low-significance transits can be “lost” for different choices of parameters that ideally should not affect the photometric pipeline’s results. In the longer term, developing an image-subtraction method that marginalizes over uncertainties of how to chose “optimal” kernels would be desirable. Pixel-level image subtraction methods that omit these parameters entirely are also worth exploring ([Wang et al. 2017](#)).

A separate point to re-emphasize is that stars in our sample must be understood to be *candidate* cluster stars, and ruling out the possibility of photometric blending is important in subsequent vetting efforts of any variable object. Careful understanding of the cluster itself is also important, as some clusters are less certain to exist than others (*e.g.*, the infrared clusters described by [Froebrich et al. 2007](#)).

<sup>8</sup> [exofop.ipac.caltech.edu/tess/index.php](http://exofop.ipac.caltech.edu/tess/index.php)

We remind the reader that our goal in creating our target catalog was completeness, rather than reliability. To create clean sub-samples, we advise using the CDEXTCAT header keyword available in the FITS files, which can be merged against the original source catalog to obtain the membership probabilities reported by the original authors. Alternatively, simply restricting the targets of interest to those with provenance from *e.g.*, the Gaia-DR2 data is another way to produce a clean sample of cluster targets.

Despite our goal of completeness, some clusters still may be missing members – the census of nearby coeval stellar populations is very much in flux. For instance, during the preparation of this work, Sim et al. (2019) identified 209 new open cluster candidates within 1 kpc through visual inspection of Gaia-DR2 data. Similarly, Kounkel & Covey (2019) searched for groups near the galactic plane within 1 kpc, and along with known clusters found hundreds of new “strings” of kinematically associated stars, which could be coeval.

Another area in which we may be incomplete is in sub-clusters of large star-forming complexes. One important example is the Orion Nebula (Messier 42; NGC 1976). While it was observed by TESS in Sector 6, searching our light curves for stars within 40 arcminutes and 100 parsecs of the Orion Nebula’s center yielded only 180 light curves, with 85 labelled members. The Orion Nebula has far more known members (Jones & Walker 1988). However, due to a combination of the spatially distributed nature of the broader complex, as well as differential extinction, the automated methods of the Kharchenko et al. (2013) and Dias et al. (2014) assigned the Orion Nebula only 44 and 326 members, respectively. Cantat-Gaudin et al. (2018) explicitly excluded young star-forming regions from their search, since the underlying assumption of their clustering method (uniformity in the field star distribution) breaks down in highly clustered star-forming regions.

In future work, these concerns will likely drive us to expand beyond the current sample of target stars. For the time being, the light curves are of sufficient quality and quantity to begin astrophysical studies. We invite any who wish to explore the time evolution of stellar or exoplanetary systems to interact with the data at [archive.stsci.edu/prepds/cdips](http://archive.stsci.edu/prepds/cdips).

NOTE— This table is published in its entirety in a machine-readable format. A portion of the transposed version is shown here for guidance regarding its form and content. Each row in the machine-readable version (each column in this version) represents a target star. The unique identifier, “ID”, is the Gaia-DR2 source identifier. The external catalog(s) claiming cluster membership is given as a comma-separated string in “Reference”, and the name they assign is given as a comma-separated string in “Cluster”. “Ext catalog name” is the name the external catalog assigns. Positions, proper motions, and the parallax are from Gaia-DR2. The magnitudes in Gaia *G*, *G<sub>Bp</sub>*, and *G<sub>Rp</sub>* bands are given. The name matching described in Appendix B most often succeeds in finding the Kharchenko et al. (2013) (K13) cluster corresponding to the external catalog claiming membership. This, or else the external name is used to assign the unique cluster name. The method for name matching (Appendix B) is also given as a string, as is a “Comment” summarizing information from Kharchenko et al. (2013) about the cluster. The age and error as quoted by Kharchenko et al. (2013) are also given.

**Table 2.** Counts of light curves per cluster in Sector 6, sorted in descending order.

## APPENDIX

## A. TIME SYSTEM &amp; BARYCENTRIC CORRECTION

The time-stamps included with the calibrated TESS Full Frame Images produced by SPOC include a barycentric correction at a single reference pixel given at the middle of every frame. The barycentric correction is at maximum 16 minutes, corresponding to points on the sky separated by 180 degrees. The angular distance from a TESS camera's center of field to the corners is  $\approx 17$  degrees, so naively one might incur at worst an error of  $\approx 90$  seconds on the time-stamps due to using a barycentric correction in a direction that is slightly wrong. Nonetheless, following Bouma et al. (2019), we perform our own barycentric correction using the appropriate sky coordinates for each light curve. We advise use of our TMID\_BJD column, which gives the mid-time of each exposure in the BJD<sub>TDB</sub> time system, which is the defacto standard in exoplanet and stellar astronomy (Eastman et al. 2010).

## B. ASSIGNING UNIQUE NAMES TO EACH CLUSTER

In assigning a single unique cluster name to each star, we matched against the Kharchenko et al. (2013) name whenever possible, since this was the largest available catalog, and it also included homogeneous age determinations for many of the clusters. To find the matching name, in order of precedence we

1. Checked for direct string matches from Kharchenko et al. (2013) clusters with determined parameters;
2. Checked whether the SIMBAD online name resolving service (Wenger et al. 2000) had any direct string matches against Kharchenko et al. (2013) clusters with determined parameters;
3. Checked for string matches in the full Kharchenko et al. (2013) index (including clusters without determined parameters);
4. Searched for spatial matches between each star and cluster centers from Kharchenko et al. (2013) within 10 arcminutes. In cases with multiple cluster matches, we ignored candidate matches to avoid assigning incorrect names;
5. Checked the WEBDA double name list<sup>9</sup>, and repeated Steps 1-4 with any matches.

A few edge-cases, including sub-clusters of larger star-forming complexes like in Sco-Cen or Collinder 33, were manually resolved to the extent feasible (Rizzuto et al. 2011 and Saurin et al. 2015 give detailed pictures of the complex morphologies that frequently arise in young star-forming regions).

The procedure described above failed to yield matches for a few of the infrared clusters identified by Majaess (2013) and included in the Dias et al. (2014) catalog. For these cases, we used the name given by Dias et al. (2014). The larger set of “FSR” infrared clusters from Froebrich et al. (2007) was incorporated to Kharchenko et al. (2013), and so did not present any complications.

The Hyades and a number of other nearby moving groups were also missed, since they were not in the Kharchenko et al. (2013) catalog. For moving groups not identified in Kharchenko et al. (2013), we adopted the constellation-based naming convention from Gagné et al. (2018b).

Finally, the procedure enumerated above did not yield matches for recently discovered clusters, such as the “RSG” clusters found by Röser et al. (2016) and the “Gulliver” clusters from Cantat-Gaudin et al. (2018). In these cases, we used the names given by the original authors.
